The diffraction techniques for particle size analysis are based on the measurement of the angular distribution of light diffracted by particles situated in the path of a light beam. These techniques have been used for many years to measure the size of small particulates but the calculation to generate a particle size distribution is so complex that it is only in the last 15 years with the development of small, inexpensive, and powerful computers that these techniques have become so popular. The complete theory describing the diffraction of light by a spherical particle was described by Mie in 1908 and is able to predict the electromagnetic field at any point in space. This theory is adequate for particles with diameters of the same order as the wavelength of the incident light. Some other models have been presented. The most commonly used are based on the Fraunhofer diffraction theory. Light-scattering techniques have obvious advantages for particle size analysis as compared to other methods. They are faster than mechanical techniques, nonintrusive, nondestructive and do not require large amounts of sample. These techniques can be performed on dry powders or on suspended particles in a liquid or in a gas. The operating range of light diffraction techniques is from 20 μm to several millimeters. This article presents the main theoretical aspects of light diffraction by particles. Also, a brief description of a diffraction particle sizer is given with some practical recommendations. Problems related to particle size analysis by light diffraction are examined. Some other light-scattering methods (photon correlation spectroscopy, single particle scattering, Doppler techniques) are also presented.

1 INTRODUCTION

Particle size is an important physical parameter in many complex systems. In many industries, raw materials are processed to be converted into finished products. The processes include grinding, sieving, mixing, and heating operations. Each of these operations is affected by the particle size. So, it is not surprising that many techniques have been developed for particle size analysis. Current methods include techniques based upon sieve analysis, microscopic and image analysis, electrical and optical sensing zones, sedimentation, elutriation, and chromatography.[1–3]

In recent years, techniques involving light-scattering for particle size analysis have become increasingly popular due to laser light sources and the development of condensed but powerful microcomputers which are inexpensive. Techniques involving light–particle interactions have certain advantages for particle size analysis compared to other methods. Also, they are easy to manipulate as many scattering instruments are considered as black boxes from a user point of view.

In fact, light-scattering techniques cover several methods, amongst which light diffraction techniques are the most commonly used. The latter are based on the measurement of the angular distribution of light diffracted by particles in a light beam path. The intensity scattered in any particular direction depends on the size of the particles and their optical properties. If the scattered light

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

is measured as a function of the angle, the resulting scattering pattern contains information regarding the particle size, which can be assessed by appropriate calculations. The extraction of this information is rather mathematically complex and will ultimately result in a particle size distribution. Particle size analysis using diffraction techniques can be performed on dry or suspended particles in a carrier. They are particularly well adapted for particles ranging from 20 to 3500 μm.

Other techniques based on light properties also provide particle size evaluations. Amongst these, we consider single particle scattering,[4] photon correlation spectroscopy,[5] or Doppler techniques.[6] The first refers to the measurement of the intensity of the scattered light from each particle individually at a fixed angle. The amplitude of the scattered light pulse is used to compute the particle size. These instruments are also called single particle optical counters (SPOCs). Photon correlation spectroscopy is designed for assessing the size of particles from 10 to 500 nm. In effect, these instruments measure the fluctuations of scattered light generated by the particles due to their Brownian motion. Since large particles diffuse more slowly than small, fluctuations in scattered light are indicative of the particle size, assuming that some essential restrictions are fulfilled.

The application of these techniques grows steadily making them increasingly popular versus traditional techniques. A few years ago, light-scattering instruments were mostly found in research laboratories, whilst now some are already inserted for on-line production control. In that sense they cover fields such as food production,[7–9] pharmaceuticals,[10] and coatings.[11]

2 THEORY OF LIGHT DIFFRACTION

When a light beam interacts with a particle, it can be absorbed, transmitted, or scattered. Scattering of light concerns the dispersion of the light beam at any angle by the particle. The theory of light-scattering by a particle has been developed by many authors, especially Mie, Rayleigh, and Fraunhofer, and has been reviewed in many books and articles.[12–14]

2.1 Mie Theory

The general theory describing the scattering of light by a spherical particle has been formulated by Mie. It allows the energy of the scattered light to be calculated as a function of the particle size, its refractive index, the wavelength of the incident beam, and the angle of observation. It is derived by solving Maxwell's equations for the incidence of a plane wavefront on a particle and is mathematically complex and does not result in simple analytical solutions. Therefore it is often necessary to make many restrictions and simplifications to become usable. Even in these conditions, proper angular distribution of scattered light is only accessible for quite simple particle shapes, such as spheres which will behave ideally. Consequently, almost all light-scattering techniques assume the particles to be spherical and provide subsequently corresponding equivalent diameters. In order to be able to obtain the scattering pattern of a particle, it is necessary to specify the refractive index of the particle, the refractive index of the suspending medium, the particle size, and the wavelength of the light beam. If for some standard materials the refractive index is an established parameter, problems may arise when biological or food products are considered. Moreover, for very small particles, the angular intensity distribution is dependent on the polarization of the incident light. As a concluding remark, it can be stated that Mie theory is applicable for particles whose size is of a comparable order to the wavelength of the incident light.

For particles shorter than the wavelength of the incident beam, Rayleigh scattering theory is available. For particles larger than the wavelength of the incident beam, Fraunhofer theory can be applied.

2.2 Rayleigh Scattering

If the particles are very small compared to the wavelength of the incident light, they can be considered as opaque points wherein light is not able to penetrate. According to the Rayleigh theory, the scattering pattern is independent of the shape of the particle, as they are considered as points. This leads to a very simple scattering pattern identical to that obtained from the Mie theory for particles of very small size. According to this theory, the scattering intensity I at an angle θ is given by Equation (1):

$$I = I_0 \alpha^2 \left(\frac{2\pi}{\lambda} \right)^4 \frac{1 + \cos^2 \theta}{2r^2} \tag{1}$$

where I_0 is the incident intensity, r is the distance from the particle to the detector, λ is the wavelength of light, and α the particle polarizability which for spheres is given by Equation (2):

$$\alpha = \frac{3(m^2 - 1)}{m^2 + 2} \frac{V}{4} \tag{2}$$

with m the relative refractive index and V the volume of the particle. The scattering intensity is thus proportional to the sixth power of the particle diameter. It follows that small changes in size will greatly affect scattered intensities. However, small particles scatter a very small amount of light. It is also understood that the study of the scattering properties of these small particles is very limited.

2.3 Fraunhofer Scattering

Fraunhofer scattering is a diffraction theory which was developed for large opaque particles. It assumes that light that has penetrated into the particles does not contribute to the diffraction pattern, so the particles are considered as completely opaque. Consequently, this theory does not take into account the optical properties of the particles. It is very useful for the calculation of the size distribution of particles of several micrometers and even higher. Most of the earlier laser diffraction instruments are based on this theory.

The Fraunhofer diffraction theory is sometimes described as the light-scattering caused by the edges of an aperture. Babinet's theorem explains that the diffraction pattern obtained with an aperture of given size and shape is the same with an opaque object (particle) of equivalent size and shape. Two requirements are needed to obtain a diffraction according to the Fraunhofer theory: the size of the aperture (or the particle) must be small in relation to the distance between its position and the light source and the diffraction must be observed at infinite distance. In that case, the diffraction patterns of particles having the same size superimpose perfectly. The first requirement can be satisfied by considering a plane wave incident on the diffraction plane. The second requirement can be satisfied by placing the detector far away from the aperture or by using a lens in order to focus the diffracted light onto a detector at the focal plane of the lens.

For a given spherical particle, the Fraunhofer theory allows the intensity of the scattered light to be defined as shown in Equation (3):

$$I = I_0 \left(\frac{2J_1(x \sin\theta)}{x \sin\theta} \right)^2 \tag{3}$$

where I_0 is the intensity of the incident light, θ is the diffraction angle, J_1 is a Bessel's function of first order, and x is a parameter, often called the size parameter, given by Equation (4):

$$x = \frac{2\pi r}{\lambda} \tag{4}$$

where r is the particle radius and λ the wavelength of the incident light.

The scattering is observed for small angles and in this case it is possible to write Equation (5):

$$I = I_0 \left(\frac{2J_1(x\theta)}{x\theta} \right)^2 \tag{5}$$

The angles for which the diffracted intensity will cancel depend on the particle size and the ring of order k corresponding to beams diffracted at the angle given by

Figure 1 Effect of particle size on the diffraction angle.

Equation (6):

$$\theta_k = \frac{\lambda}{2\pi r} m_k \tag{6}$$

where m_k is the value for which the function J_1 is equal to 0. The radius of a diffraction ring is conversely proportional to the particle diameter. It follows that small particles will scatter light at larger angles, whereas large particles scatter at smaller angles (Figure 1).

The diffraction pattern of the light onto the detector will exhibit intensity variations as a sequence of minima and maxima (Figure 2a) which correspond to a series of concentric rings alternately dark and bright, with a more intense disk at the center (Figure 2b).

Figure 2 (a) Scattering intensities and (b) corresponding scattering pattern for a circular particle.

The particles are not analyzed individually. The intensity at the detector is the result of the light diffracted by the particles in the analyzed sample whatever their size as defined by Equation (7):

$$I = C \int_0^{\infty} N_{(r)} r^4 \left(\frac{J_1(x\theta)}{x\theta} \right)^2 \mathrm{d}r \qquad (7)$$

where $N_{(r)}$ represents the population of particles of size r and C is a constant. The size classes and the angles for which the diffraction is measured are fixed. The diffraction model is an additive model for which the constants are fixed by the instrument and the unknown parameters are the ratios of the distribution. Mathematical algorithms are required to transfer light intensities into particle sizes. For polydisperse systems the diffraction pattern of each particle size overlaps with those of the same order in the system. As a consequence, the mathematical algorithms and necessary assumptions required for the calculations are very complex. For the instruments available, these algorithms are strictly confidential and in general fit between observed and theoretical intensities which will be obtained by a population of spherical particles.

3 DESCRIPTION OF A LASER DIFFRACTION PARTICLE SIZER

In Figure 3, the principle of a diffraction particle sizer is illustrated. The light source is a helium–neon laser generating light at a wavelength of 633 nm. It provides a better stability and a higher signal-to-noise ratio than lasers with higher wavelength. The beam diameter is about 1 mm, so a beam expander is mounted in order to produce a uniform parallel beam of nearly 10 mm in diameter in order to monitor a useful sample volume. The expanded beam passes through the sample cell and the diffracted and transmitted light is focused by a lens onto the detector in the focal plane of the lens. The latter is often a Fourier lens providing a Fourier transform image of the scattered light. Every parallel light beam emitted from the sample at a given angle θ will be focused in the focal plane at the same azimuth and at a position $X = F(\theta)$ (Figure 4). This very interesting property means that the diffraction will be independent of the position of the particles in the light beam. The undiffracted light is focused at the center of the detector and evacuated through a pinhole. The detector generally consists of photosensitive silicon rings with increasing widths. Since the light scattering at large angles may be several orders of magnitude less than that near the center, the external rings should have a subsequent higher sensitivity or surface. The signal at a specific position on the detector corresponds to the light intensity scattered

Figure 3 Schematic of a laser diffraction instrument.

Figure 4 Schematic of Fourier transform lens.

at a definite angle, whatever the position of the particle in the sample cell. The smaller particles detected are estimated at 1 μm. The focal length sets the size of the diffraction field and then the range of measurements. A large focal length enables the resolution at the center of the diffraction rings to be improved, allowing larger particles to be analyzed.

4 PRACTICAL MEASUREMENTS

4.1 Particle Size Range

The lower diffraction limit will correspond to the limit of validity of the geometrical laws of optics. It will be influenced by the relative refractive index of the particles. For water, this value is set at 1.33. When the relative refractive index is closer to 1, this limit can increase. The upper limit of size analysis by diffraction is due to the lack of resolution near the central bright point on the detector.

4.2 Sample Preparation

The samples should have homogeneous physical properties (refractive index, volumetric mass, etc.). For measurements in the liquid phase, the choice of the suspending medium is very important. The dispersion

can be facilitated by ultrasound or with appropriate additives. However, the dispersion method should not modify the sample. The refractive index of the powder must differ from that of the suspending medium. It must be transparent to the incident laser beam and the refractive index must be stable during the experiment. The main cause of variations of the refractive index is temperature changes. These variations lead to a contribution of the small angles corresponding to an overestimation of the larger particle sizes. If large particles are to be measured in a suspending medium, the flow rate should be set to the minimum value that will allow them to be suspended without sedimentation. Sufficient time should be allowed for a perfect mixing of the suspension before a measurement. The most commonly used suspending media are water, methanol, ethylene glycol, and trichloroethylene.

Dry powders can be analyzed by sending the sample through the laser beam when free-flowing. The dry powders are blown through the light beam by compressed air and evacuated by a vacuum cleaner. If the particles are cohesive, the material may not be properly dispersed. The advantage of dry measurements is that the quantity of sample analyzed is not limited. It is then possible to perform a measurement from 100 mg to several kilograms with a continuous flow rate. This may avoid the preparation of a representative sample, which is often a critical step.

Laser diffraction is also particularly well adapted for aerosol sizing since many liquid droplets measure several micrometers. It is necessary to spray the aerosol into the laser beam during the measurement.

4.3 Sample Amount

The sample amount does not play a part in the measurement, except for the representativeness. However, for measurements in a liquid phase, an optimal concentration of the sample in the suspending medium is needed to avoid multiple scattering problems (see below). Most of the commercially available instruments set the concentration in the sample cell by measuring the light absorbed by the sample. The optimal concentration is obtained for an absorbance of 0.1–0.25. If the concentration is too low, too few particles are measured and the statistical errors predominate. Generally, the quantities required for an optimal measurement are about 1–2 g for liquid measurements, and 20–40 g for dry measurements.

4.4 Experimental Measurements

The focal lens is chosen according to the range of particle size studied. An analysis consists first of taking data for the background and then for the sample. The background is subtracted from the sample signal. Both measurements need to be done in the same operational conditions. This is easily done for a measurement of a suspension in a liquid. The background is acquired by injecting the suspending medium alone. Then the particles are added to the sample cell. A protocol is established for each kind of powder which determines the stirrer speed, the pump speed, the air pressure, the use of ultrasound, etc.

4.5 Results

We have seen above that it is possible to calculate the scattering pattern from a sample of known size distribution by using a particular theory (Mie, Rayleigh, Fraunhofer). It is also necessary to solve the inverse problem in order to obtain a particle size distribution from a scattering pattern. From a practical point of view, it is almost impossible to find the particle size distribution from the scattering pattern by applying only simple algebraic operations.

In fact, a first distribution is roughly calculated from the scattering pattern by examining any maximum of intensity in that pattern. Then the scattering model that would be obtained from that distribution is calculated by using the appropriate model. The difference observed between the calculated and the experimental pattern are used to correct the distribution. This procedure is applied until the difference between the two patterns is a minimum.

The transformation of light intensities into a size distribution can be done by assuming an a priori distribution shape (normal or log normal distribution for instance) or by fitting each class of particle size in the

Figure 5 Particle size distribution obtained with a laser light diffraction apparatus. Sixty-four size classes are calculated. The line corresponds to the cumulative percentages. The histogram represents the percentage of particles in each size class.

distribution independently of each other. In many cases, the distribution shape is not known. This is particularly true when the particles are heterogeneous in size and the distributions are multimodal. The size distribution obtained by laser diffraction is expressed in percentage of mass or in volume (by assuming that the density of a particle is independent of its size).

Figure 5 shows an example of particle size distribution obtained with a laser light diffraction instrument. The results can be expressed either as the cumulative percentages of particles or by the percentage in each particle size class.

5 PROBLEMS RELATED TO SIZE ANALYSIS BY LIGHT DIFFRACTION

Even though diffraction techniques have numerous advantages over other techniques, they also suffer from a large number of potential sources of systematic errors, particularly when calculating the particle size distribution. The factors which may cause inaccuracies of particle size distribution obtained by diffraction techniques are the following:

- the Fraunhofer diffraction cannot be applied to small or transparent particles. The Mie theory requires some optical properties of the particles to be known (for example the refractive index) which may not be easily accessible for the user;
- influence of the particle shape on the diffraction pattern, which may lead to an overestimation of the larger particles caused by large-angle diffraction due to the presence of edges on the particles;
- overlapping of the size classes in polydisperse systems leading to misinterpretation of the diffraction pattern;
- unknown computer algorithms for transforming the diffraction pattern into a distribution, which could vary from one manufacturer to another.

5.1 Submicrometer Measurements

As the Fraunhofer theory does not apply to systems composed of particles whose sizes are not significantly larger than the wavelength of the incident light, the examination of submicrometer particles by Fraunhofer methods is questionable. Some authors have shown sizing error greater than 20% in the mean diameter for particles in the 2–7 μm range.[15] This is due to the fact that the scattering of the smallest particles is extremely weak. This is not such a problem if only small particles are present in the system. However, when small particles are mixed with larger ones, whose scattering is many times stronger, the smallest particles may not be detected on the scattering pattern. The use of the Mie theory to solve the problem of submicrometer particles, while a possible improvement, is not always satisfactory as the optical parameters required for the necessary calculations may be unavailable. Particularly, it is often impossible to know the refractive index of the particles in complex systems. To measure the size of very small particles, photon correlation spectroscopy can be used if the particles are in suspension and do not sediment.

5.2 Particle Shape

As indicated previously, the diffraction pattern can only be analyzed for simple shapes. For complex or irregular particles, it should be interpreted with caution.[16,17] Nathier-Dufour et al.[18] have shown that particles having complex shapes (nonspherical) exhibit diffraction patterns containing large-angle scattered beams. If Fraunhofer theory is used to calculate the particle size distribution then the proportion of small particles may be overestimated. If particles of a given size are very irregular, the size distribution may exhibit artefact peaks indicating that more than one particle size is present in the sample. A shape factor may be proposed for nonspherical particles to correct for the effect of the shape on the scattering pattern but this implies that all the particles in a given sample have the same shape.

5.3 Multiple Scattering

The light-scattering models assume that each photon encounters only one particle. When a photon is scattered by a series of particles, its incidence angle will be known only for the first encounter and then the scattering pattern could not be interpreted. This phenomenon is called multiple scattering and is highly undesirable in many cases. It results in larger diffraction angles, since light scattered once is no longer parallel when it encounters another particle. This leads to an overestimation of the small particles. To ensure that no multiple scattering occurs, it is important to keep the sample perfectly dilute.

5.4 Calibration

Laser diffraction instruments do not need calibration in the usual sense. The diffraction pattern can be converted into a size distribution without standard measurements since they are based only on fundamental physical properties. It is however important to regularly check the instrument performance in order to ensure that it gives a relevant particle size distribution. This can be done by measurements of the monodisperse standards distribution covering the range of the instrument. The most generally available standards are latex particles.

5.5 Data Processing Artefacts

Generally, the fitting models are accurate for monodisperse samples in the center of the measuring range. For polydisperse systems, particles having close sizes will lead to an overlapping of their diffraction pattern. For commercially available instruments, the algorithms used for the transformation of the diffraction pattern into a distribution are unknown to the user. The manufacturer's assumptions and their effect on the resultant particle distribution are not generally verifiable. Moreover, the calculations are so complex that approximate theories or iterative methods are used and each manufacturer provides its own algorithm which may lead to differences in the results from different instruments using the same sample. It is then always necessary to compare particle size distribution obtained by laser diffraction with other independent methods.

5.6 Intercomparison of Laser Diffraction Instruments

Some work has been done to compare results of various laser diffraction instruments. For instance, Etzler and Sanderson[19] have shown that different Fraunhofer instruments could produce largely different particle size distributions from the same material. This indicates that the results obtained from any given instrument may not accurately describe the powder and thus may lead to incorrect technical recommendations. These authors suggest the results obtained with one laser instrument should be compared with those of an other independent method to insure against the presence of instrumental artefacts.

6 OTHER LIGHT-SCATTERING METHODS FOR PARTICLE SIZE ANALYSIS

6.1 Single Particle Scattering

The principle of single particle scattering instruments is very simple. The particles are passed in an air jet through a light beam and scatter a light pulse whose duration is proportional to the time taken to pass through the beam and whose intensity depends on particle size. These instruments are called SPOCs. They are well adapted for particles with sizes up to about the wavelength of light. They offer the advantage of providing an absolute concentration in terms of the number of particles per unit volume. However, since each particle is analyzed separately these instruments are slower than Fraunhofer instruments which average the particle sizes over the particles present in the sample.

6.2 Photon Correlation Spectroscopy

Photon correlation spectroscopy, also known as quasi-elastic or dynamic light-scattering,[20] is a method of size measurement for suspensions of spherical particles in the 20–500 nm size range. In a typical photon correlation spectrometer, particles are illuminated by a laser beam. The scattered light is detected at an angle θ with respect to the incident direction. Since the particles are continuously displacing due to Brownian motion, the observed scattered intensity will fluctuate along the time axis. Therefore, the analysis of these fluctuations as a function of time provides information on the mobility of the particles. This mobility is related to the diffusion coefficient and the latter to the particle radius. Since large particles diffuse more slowly than small ones, the fluctuations in scattered light intensity from large particles occur over a longer timescale than fluctuations induced by small particles. The problem for photon correlation spectroscopy is to extract the quantitative information from the fluctuations. This can be done by an autocorrelation analysis. The autocorrelation function $G(\tau)$ of a fluctuating intensity is defined in Equation (8) as the product of the intensity at an instant t and the intensity at an instant $t + \tau$:

$$G(\tau) = \langle I(t)I(t+\tau)\rangle \tag{8}$$

This correlation function depends only on the time difference τ and is independent of the arbitrary time t. The symbol $\langle\cdots\rangle$ indicates that G is an average of $I(t)I(t+\tau)$ for various times t.

For monodisperse small spherical particles, this autocorrelation function is essentially an exponentially decaying function of the time difference τ and can be written as shown in Equation (9):

$$G(\tau) = A + B\exp(-2Dq^2\tau) \tag{9}$$

where A and B can be considered as instrumental factors and D is the diffusion coefficient, with q being given by Equation (10):

$$q = \frac{4\pi n}{\lambda}\sin\left(\frac{\theta}{2}\right. \tag{10}$$

with n the refractive index of the medium, λ the laser wavelength, and θ the scattering angle. The particle size is obtained by relating it to the diffusion coefficient. However, there is no general relation that applies in all situations. With the assumption that the particles are spherical and noninteracting, the particle diameter d is obtained from the Stokes–Einstein equation shown in Equation (11):

$$d = \frac{kT}{3\pi\eta D} \tag{11}$$

where k is the Boltzmann constant, T the absolute temperature, and η the shear viscosity of the solvent.

For a polydisperse system, the size distribution is obtained by deconvolution of the sum of all the single exponentials contributing to the measurement of the autocorrelation function.

6.3 Laser Doppler Velocimetry

Laser Doppler velocimetry is a velocity measurement technique based on the Doppler shifting properties of moving particles, as they interact with light. In laser Doppler velocimeters, the laser beam is divided into two and the focusing lens forces the two beams to intersect, creating interferences (Figure 6). The interferences of the light beams in the measurement volume create a set of equally spaced fringes (light and dark bands) that are parallel to the bisector of the beams. A measurement is made when a particle being carried by the flow passes through these fringes. The light scattered by the particle will have a frequency (the Doppler frequency) proportional to the fringe spaces and to the component of its velocity normal to the fringes.

Two main techniques can be used to relate the Doppler frequency to the particle size. The first method is based on the interpretation of the Doppler signal shape generated by a particle moving through the fringes, which depends of the ratio of the particle size upon the interfringe space. However, this method leads to good results only if the Doppler signal is of good quality. As a consequence, this method is often replaced by the phase Doppler technique.

In phase Doppler velocimeters, multiple detectors are used to collect the light scattered by a single particle. The principle is that if two light sources of the same frequency, but at different angles, are scattered from a single moving particle, the light reaching the detectors will have the same frequency but phase Doppler shifts. This is a result of the fact that when a particle passes through the beams, it does not uniformly illuminate the receiving lens. The diffraction pattern passes over it from one side to the other. As a consequence, the signal will be received in the detectors at slightly different times, i.e. the separate detector signals are out of phase. These phase differences can be related to the particle size if the relative refractive index of the particle is known. For particular positions of the detectors, the relation between the phase shift and the particle size can be considered as linear.[21] The phase Doppler method requires no calibration because the particle size and velocity are dependent only on the laser wavelength and on the optical configuration. Phase Doppler measurements are not based upon the scattered light intensity, and consequently, are not subject to errors from beam attenuation or deflection.

Figure 6 Schematic of a laser Doppler anemometer.

7 CONCLUSION

This article has attempted to show the main advantages of particle analysis by light diffraction in terms of usefulness, rapidity, and performance. This technique can be used for particles ranging from 1 μm to more than 3000 μm. It can be adapted for dry or suspended particles in a liquid phase, for aerosols and emulsion. It is a nonintrusive and nondestructive technique, very easy to use even if the mathematical theories to obtain a particle size from the diffraction pattern are very complex. The results are obtained very rapidly (less than 1 min to obtain a particle size distribution) with good repeatability. With all these advantages, it is not surprising that light diffraction techniques are being increasingly used for particle size analysis and will replace ''traditional'' techniques in many fields in the coming years.

Particle sizing is a rapidly growing field, not only because of its importance in a great variety of technological applications but also due to its outstanding relevance to numerous areas of scientific research.

The currently available instruments to measure particle-size distributions are many and varied, the results often being dependent on the measuring technique used. It is thus essential to understand the physical principles behind each technique in order to make an adequate choice.

Electrozone sensing, a widely used method of particle-size analysis, constitutes the main topic of this paper. A general description of its operating principle is provided, followed by some practical considerations mainly concerning sample preparation and the selection of electrolyte solutions and aperture tubes. Being a technique that requires prior calibration, emphasis is placed on the calibration procedures. The section dedicated to the measurement of special materials also reviews some recent improvements of this technique. Finally, a list of commercially available equipment is supplied, together with its most relevant features.

1 INTRODUCTION

Almost every solid material either starts out as a powder, ends up as a powder, or goes through at least one powder stage during manufacture. It is thus not surprising that powder technology plays such an important role throughout process industries, including areas as diverse as chemicals, foods, agricultural products, mineral processing, ceramics, cements, advanced materials, defense, and the environment. In the chemical industry, for example, 60% of the products are manufactured in particle form and a further 20% use powders to impart specific properties to the final products.[1] Moreover, it has been widely recognized that the behavior and properties of the end products are highly dependent upon the characteristics of the particles from which they are formed, namely particle morphology (shape and texture), size, and size distribution.[1,2]

With regard to particle sizing, it should be kept in mind that, for irregular particles, there is not a unique size and that the equivalent-sphere approach is method dependent[3] – in effect, differences between sets of data obtained for irregular particles by different measuring techniques constitute relevant information on particle shape, rather than representing an error.[4] Therefore, a proper knowledge of the method of measurement, and in particular of the equivalent spherical diameter measured, is essential for the adequate use of the data.

In principle, any aspect of particle behavior which is dependent on particle size can be used to measure that size. This explains, at least partly, the great variety of instruments commercially available which, despite their differences in configuration and degrees of sophistication and automation, are based on only a few physical principles.[3]

Electrozone sensing (also named the electrical sensing zone method) is the most widely used of the so-called *stream scanning methods* where particles are measured one at a time. In these methods, particle size is determined by the interaction between the particles and an external field which can be an electrical field (electrozone sensing) or a light beam (optical sensing). Electrozone sensing was originally developed by Wallace Coulter (and so is frequently known as the 'Coulter principle') in the late 1940s for counting blood cells rapidly, but was only patented in 1953[5] and described in detail much later.[6,7] It has become very popular not only for counting and

sizing blood and other cells and organisms, but also for measuring the particle-size distribution of a wide range of particulate materials as drugs, pigments, fillers, toners, foodstuffs, cosmetics, explosives, construction materials, minerals, coatings, metals, and polymeric powders.

Electrozone sensing is the only method that measures a particle volumetrically, i.e. in three dimensions, and thus is less sensitive to particle shape, in contrast to optical sensing – indeed it is reasonably independent of this parameter, except for extreme shapes such as flaky particles. Additionally, the analyses can be carried out rapidly and with good reproducibility by semiskilled operators. As a result, this method has been the subject of a large number of studies and applications (biological and nonbiological),[8,9] and is extensively described in textbooks.[10] The technique has been accepted as a standard method by the British Standards Institution,[11] as an AFNOR standard[12] and, more recently, by the International Organization for Standardization (ISO),[13] in addition to being recommended for many special applications.[8]

As with other particle sizers, electrozone sensors have advanced significantly and the modern apparatus exhibits a range of specific features, including the storage, handling, and presentation of data. In particular, the main advantages of this technique are:

- it measures particle volume (one of the most representative expressions of particle size), for which it is often used as a reference method;
- the instrument response is not influenced by particle composition, density and refractive index or light interaction effects (inherent to many light blockage/scatter and diffraction systems);
- it produces accurate counts and high-resolution particle-size distributions;
- it is able to measure absolute concentrations (number or volume of particles per total volume of suspension).

The basic limitations are:

- the need to suspend the particles in an electrically conductive fluid;
- the necessity of prior calibration which, depending upon the degree of accuracy, can be laborious and, consequently, time-consuming;
- the limited size range (about 30 : 1 by diameter) covered by a single aperture, which requires the use of more than one aperture for very broad size distributions.

In summary, electrozone sensing presents a good combination of high resolution, size range, sensitivity, and mildness of secondary effects, and has been extensively used to measure particles from about 0.5 μm to approximately 1 mm, the upper limit depending mainly on particle density.

2 PARTICLE DETECTION PRINCIPLE

2.1 General Operation

In the electrozone measurement principle, particles homogeneously suspended at a low concentration in an electrolyte solution are forced to flow, substantially singly, through a small aperture (or orifice) in a nonconductive material that separates two electrodes of opposite potential (Figure 1). A current passing through the aperture between the electrodes enables the particles to be sensed by the changes in electrical impedance as they traverse the aperture.

The passage of a number of particles produces a train of pulses whose amplitudes are essentially proportional to the particle volumes. These pulses are then amplified, sorted, and counted. After instrument calibration, a distribution of the number of particles against volume, or equivalent volume diameter (usually denoted by d_v), can be obtained. This distribution is in turn easily converted

Figure 1 Electrozone sensing operating principle. (Reproduced by permission of Beckman Coulter.)

to a volume-based distribution of d_v. As the volume of a particle is directly related to its mass through the density, the latter distribution is identical to a mass distribution for particles of uniform density.

The sample to be analyzed is dispersed in an electrolyte solution which is placed in a beaker and stirred. An orifice tube (a closed-end glass tube containing a precision-drilled hole) is immersed in the suspension and the flow through the orifice, controlled by a vacuum source, unbalances a mercury manometer (Figure 2).

Originally, all analyses were performed in the *manometer* (or *siphon*) *mode*. In this mode, the system is isolated from the vacuum unit but the flow continues as the mercury returns to equilibrium. The advancing column of mercury activates start and stop contacts, placed so that the count is carried out in a precise and reproducible volume of suspension (usually 0.05, 0.5 or 2.0 mL). This mode is therefore most useful for measuring particle concentration values (number or volume per total volume). Most modern instrumentation also operate in the *manual mode*, where data are acquired by manually initiating and stopping the counting, or in the *time* or *count mode*, in which the counting ends when the time period or the count reaches a preselected value.

As particles pass sequentially through the aperture, each displaces a volume of electrolyte equal to its own immersed volume producing a change in the resistance between the electrodes. As the current is maintained constant, these changes produce voltage pulses of short duration whose heights are essentially proportional to the volume of the particles. The pulses are amplified and fed to a threshold circuit having an adjustable threshold level. When this level is reached or exceeded by a pulse, the pulse is counted. (In some apparatus, the threshold level can be visualized on a small oscilloscope screen, facilitating the selection of appropriate counting levels.) The number of pulses counted represents the number of particles larger than some determinable value – the threshold value is related to the equivalent particle diameter through a calibration constant. In the simple models (called single-channel models), the usual procedure is to reset the instrument and initiate another count at a different threshold. Other instruments have upper and lower threshold circuits which permit sizing between two predetermined volumes (i.e. relative frequency distribution). Normally, in single and dual models, data are manually converted to the volume (or mass) distribution. More recent models are capable of multichannel analyses, i.e. the results can be simultaneously accumulated at a number of channels (size levels), typically between 16 and 256, in a very short time. The main advantages of multichannel analyses are the saving of operator time by removing repetitive counts and the ability to store the data in an internal or external computer for further processing. However, some authors claim that in some of these models a loss of counts may occur.[10,14] This is because it takes a finite time to process each pulse and, especially for relatively high count

Figure 2 Diagram of the electrozone sensing analyzer.

rates, it is possible that a significant proportion of counts may be lost. In general this will not affect particle-size distributions.

2.2 Sizing Response

Electrozone sensing measures particles by volume, assuming that the height of the pulses generated is directly proportional to the volume of the particles producing them. The reliability of the instrument therefore depends on the accuracy of this assumption. The relationship between the instrument response and particle size has been the subject of several theoretical models,[15–20] as there is no precise and simple solution with which to determine the change in resistance caused by the insertion of a nonconductive sphere in a conductive circular orifice.

This increase in resistance will be determined here using a simplified theory for ease of understanding.[16] Figure 3 shows a particle passing through the orifice and an element (slice) of the particle and orifice.

The resistance of the element without the particle is (Equation 1)

$$\delta R_0 = \frac{\phi_f \delta l}{A} \tag{1}$$

and the resistance of the element including the particle can be seen as two resistors in parallel (Equation 2):

$$\delta R = \frac{1}{A - a/\phi_f \delta l + A/\phi_s \delta l} \tag{2}$$

where A is the cross-sectional area of the orifice, a is the cross-sectional area of the particle, ϕ_f is the resistivity of the fluid, ϕ_s is the resistivity of the particle, and δl is the element thickness. Thus the resistance change due to the presence of the particle is (Equation 3)

$$\delta(\Delta R) = \delta R_0 - \delta R = -\frac{\phi_f a \delta l}{A^2}\left(1 - \frac{\phi_f}{\phi_s}\right)\frac{1}{1 - (1 - \phi_f/\phi_s)a/A} \tag{3}$$

Assuming a constant current I across the aperture, the voltage pulse generated is $I\Delta R$.

Theoretically, the response depends on the resistivity of the particle; however, this is rarely observed due to particle surface phenomena which render the particle resistivity practically infinite.[16] The quotient of the resistivity in Equation (3) is therefore negligible compared to unity, giving (Equation 4)

$$\delta(\Delta R) = \frac{-\phi_f a \delta l / A^2}{1 - a/A} \tag{4}$$

For spherical particles the change in resistance can be derived by integrating Equation (4), which yields (Equation 5)[10]

$$\Delta R = \frac{8\phi_f d^3}{3\pi D^4}\left[1 + \frac{4}{5}\left(\frac{d}{D}\right)^2 + \frac{24}{35}\left(\frac{d}{D}\right)^4 + \cdots\right] \tag{5}$$

where d and D are the particle and the aperture diameters respectively. As can be seen in this equation, the response increasingly deviates from linearity as particle size approaches aperture diameter. Errors due to neglecting diameter powers higher than d^3 have been calculated for various shapes.[15,16]

Other theories have been proposed based on the Maxwell equation for the composite resistivity of a dilute suspension of insulating spheres in a conductive solution.[17–19] This can be written in the general form of Equation (6)

$$\Delta R = \frac{\phi_f v}{A^2} F \tag{6}$$

from which it is evident that the instrument response is proportional to the volume of the particle v, modified by the function F which depends on particle shape and size. Although containing unequal powers of d and D, most formulas proposed for F predict a constant value, i.e. a linear response for a particular aperture if the ratio d/D is much less than unity. However, significant deviations are indicated for large values of this ratio. Nonetheless, more recent experimental studies, carried out with constant-current instruments, showed linear particle responses up to 80% of the aperture diameter, for latex spheres.[21,22]

For grossly irregular shapes it has been recognized that this parameter has a considerable effect, and a self-calibration of the instrument (discussed later) is required which, nevertheless, will hold over the measuring range

Figure 3 Passage of a particle through the aperture.

of the aperture.[21,23] In any case, in practice, ratios of d/D exceeding 0.6 should be avoided as aperture blockage becomes too troublesome.

In addition to particle size and shape, the instrument response is also influenced by the inhomogeneous electrical field, or current density, in the aperture.[24] In effect, the passage of the particles through regions where the field is not uniform will give rise to relationships between particle volume and resistance change that are more complex than that of Equation (6). A normalized pulse height topography in and near an orifice with a length (i.e. thickness) equal to its diameter is illustrated in Figure 4. As can be seen, pulse height and shape depend on the path of the particle through the orifice – for example, at the orifice inlet and outlet edges characteristic double-peak shapes are obtained, whereas those pulses from the center flow of the aperture possess a bell shape. Longer tubes generate nearly homogeneous fields in the central core of the aperture. Figure 4 also shows that the sensing zone of the orifice is not restricted to the orifice itself.

One way of eliminating these distorted pulses, and which is available in certain models, is to electronically edit them; that is, the pulses are examined and only those that conform to a reference pulse shape parameter (e.g. height to width ratio) are accepted.[25] In some circumstances, this can also lead to a considerable loss of pulses which, in turn, is compensated by an improvement in the distribution resolution (discussed later). An alternative, that avoids the rejection of so much information, is to reshape pulses using mathematical equations.

Figure 4 Pulse height distribution in and near an orifice of thickness equal to diameter. The maximum pulse height in the axial path is 96% of that in a homogeneous field. (Reproduced by permission of Wiley-VCH from V. Kachel, *Part. Charact.*, **3**, 45–55 (1986).)

2.3 Correction for Coincident Passages

Ideally, the particles should traverse the aperture singly. However, there are inevitable probabilities of multiple-particle passages, which can result in two types of errors (Figure 5).

- *Primary coincidence* – two (or more) particles simultaneously present in the sensing volume may be counted as only one, depending on their proximity and on the instrument electronic resolution.
- *Secondary coincidence* – two very close particles, which individually originate pulses below a given height level, may collectively be sized as one particle well above that level.

As particle-size distributions should not be a function of concentration, the coincidence effect can be tested by comparing a distribution at one concentration to that at a lower concentration. Primary coincidence can be corrected mathematically, as explained below. Nevertheless the use of extremely dilute suspensions is recommended, as these will reduce both types of coincidence errors.

Several coincidence theories varying in complexity have been used.[26–28] Most are based on the Poisson distribution of probabilities, in which the relationship between the true count N and the observed count n is (Equation 7)

$$n = \frac{V_m}{V_z}\ 1 - \exp\left(-\frac{V_z}{V_m}N\right) \tag{7}$$

where V_z is the sensing zone volume and V_m the metered volume for each count. It should be emphasized that the effective volume of the sensing zone exceeds the physical

Figure 5 Effect of coincidence on count and size recorded.

Figure 6 Cross-sectional representation of the aperture, showing the effective sensing volume.

edges of the aperture itself, as indicated in Figure 6 – in many cases V_z is approximately 2.5 times the aperture volume.[16,21]

Equation (7) can be rearranged (Equation 8) as

$$N = -\frac{1}{\alpha} \ln (1 - \alpha n) \tag{8}$$

where (Equation 9)

$$\alpha = \frac{V_z}{V_m} \tag{9}$$

The unknown α can be eliminated by solving simultaneous equations obtained for different dilutions.[28]

Usually simplifications of Equation (7) are utilized, as for example Equation (10)[27]

$$n = N - cN^2 \tag{10}$$

where c is a constant related to the aperture size and sampling volumes, being determined experimentally.

The use of the Poisson distribution model to predict coincident losses has been questioned, especially for higher concentrations, and a more convenient algorithm has been proposed[29] that does not need a quadratic solution, as required by Equation (10).

Published data on coincident correction are sometimes contradictory and frequently depend on the instrument and on the aperture tube. However, providing that the concentrations are kept quite low (below 5% coincidence) almost all coincidence theories yield similar corrections. Most modern instruments make these corrections automatically.

Electronic pulse editing can also remove coincident passage pulses, as these have similar width and shape characteristics to edge-effect pulses.

2.4 Precision, Accuracy, Resolution and Sensitivity

Being a method frequently used as a reference, electrozone sensing should be capable of high precision, both in terms of repeatability and reproducibility, and accurate measurements. Its resolution and sensitivity should also be adequate to detect slight changes in particle-size distributions.

Although there is not much information on this subject in the literature, it is recognized that, for many particle-sizing techniques, repeatability is highly dependent upon sampling and/or dispersion of the powder and on the number of particles. For electrozone sensing measurements, a minimum count of 100 000 particles is recommended for obtaining good repeatability in the volumetric size distribution[13] – e.g. standard deviations less than 1–2 μm are expected for median sizes of moderately wide distributions of particles smaller than 100 μm. As for reproducibility, and despite written standards being available for this method, different operating and/or calibrating procedures may result in significant errors.[30]

As these analyzers are usually calibrated with certified materials (as described later), the accuracy of the analysis is related to the precision of the calibration. This is governed essentially by the quality of the calibrating material and by the constancy of the calibration constant, both in time and over the measuring range – the accuracy of the calibration constant is usually about 0.5–1% for apertures below 100 μm.

Another important aspect of particle sizing is resolution, which is the ability to differentiate between two closely situated peaks or the ability to measure very narrow size distributions. The resolution of the early models was limited by the number of channels available. In modern multichannel analyzers, however, size distribution analyses may be performed using up to 256-channel resolution. In addition, data may be re-expressed as windowed data for even greater sizing resolution. Hence, the resolution now is normally limited by effects such as coincident particle passages and electronic field inhomogeneity. Several methods have been devised for improving the resolution of electrozone sensors, such as electronic pulse editing and the use of longer than conventional apertures. Pulse editing also enables particles to be resolved from baseline noise,[25] thus improving the quality of the measurements – in most situations where about 100 channels are used independently over the measuring range, a typical resolution of 0.1–0.5 μm is anticipated in the measurement range below 100 μm, which is high in comparison to many other techniques.

In the absolute sense, sensitivity can be defined as the number or volume of particles that differs significantly from blank electrolyte. For electrozone sensing the sensitivity is generally very good. Depending on the size of the particles, the sensitivity usually ranges from single particles (at larger sizes) to a few hundred (at small sizes) per size class and per milliliter of liquid sampled.

3 ANALYTICAL CONSIDERATIONS

As previously discussed, the amplitude of the pulses originated by the passage of the particles through the sensing zone is essentially proportional to particle volume, provided that certain conditions are fulfilled:

- particles should be adequately dispersed and homogeneously suspended in the beaker;
- the orifice diameter should be at least twice that of the largest particles to reduce blockage and nonlinear response;
- particle concentration should be low to minimize coincident passages through the orifice;
- particle diameters should give a signal above the noise level (which is normally obtained for $d/D > 0.02$).

The aim of this section is to supply some information regarding operational procedures so that these conditions are accomplished.

3.1 Sample Preparation

The quality of any particle-size analysis result is greatly influenced by the accuracy and reproducibility of the sampling and dispersing techniques. Generally, the quality of the measurement depends on how representative the sample is of the bulk from which it is drawn. In many cases the analyst is presented with laboratory material, the sampling of which he has no control over. Then there is often the need to reduce the laboratory sample to quantities suitable for particle-size analyses, it being therefore indispensable to ensure the homogeneity of the material throughout subdivision. Various devices have been developed for taking samples from the bulk of a powder and for splitting primary samples to smaller ones.[10,31] The spinning riffler has been widely used for this purpose. In this instrument, the powder delivered from a hopper by a small vibratory feeder falls on to a succession of receivers mounted on a rotating table. Sampling an agitated suspension with a syringe or pipette is also a good method for the preparation of very small measurement samples (like those required for electrozone sensing). However, for coarse powders (>20 μm), concentration gradients and particle segregation due to settling may lead to selective sampling. Suspension samplers with multiple capillary tubes have been designed to eliminate these errors. Whichever method is adopted, it is recommended that its efficiency is checked.

The material under test should be well dispersed because the presence of agglomerates generates untrue size distributions and is often connected with poor repeatability of the results. In some cases the test is related to the state of dispersion in an application, so that the quantity of agglomerates is the reason for the measurement. Ideally, the following requirements have to be met:

- the solid particles should exist in the suspension individually (i.e. free of agglomerates);
- the dispersion state should not be modified during the time of the analysis.

If a dry powder is to be used for preparation of a suspension, it should be spatulated with a few drops of a suitable dispersant and slowly diluted with the electrolyte solution. Further dispersion with ultrasonic energy is normally used, except for very fragile or biological materials. It is always important to indicate clearly the specific protocols adopted for both sampling and dispersion.

A microscopic examination of the suspension should be carried out prior to the analysis, to check the degree of dispersion and to estimate the size range of the particles. This is necessary to select the most adequate aperture tube.

The stability of the dispersion during the analysis time should be checked by comparing repeat analyses, using a multichannel counter if possible. This type of instrument is particularly useful to study this phenomenon, owing to the rapidity with which the analyses can be performed. Table 1 shows some symptoms of instability and its main causes.[11,32]

Suitable agitation should also be assured by adjusting the stirrer speed to maximum effect without entraining air bubbles.

3.2 Choice of Electrolyte Solution

Electrolytes for electrozone measurements must have suitable electrical conductivity and physicochemical neutrality towards the particles. A list of the most useful electrolytes as well as dispersants and their applications is usually supplied by the instrument manufacturers and

Table 1 Dispersion instability and possible causes

Change in count[a]		Symptom
Maximum size	Minimum size	
+	+	Crystallization; precipitation
−	−	Dissolution
−	+	Size reduction; deagglomeration
+	−	Agglomeration
−	0	Settling of larger sizes

[a] + denotes count increase, − denotes count decrease, 0 denotes no change.

is also available in the literature.[11,32] For a given material, the electrolyte used must not cause the particles to agglomerate, react, dissolve, disintegrate, shrink, or swell.

Aqueous media are widely employed because the great majority of materials are water insoluble or only slightly soluble. An electrolyte solution of about $10\,g\,L^{-1}$ sodium chloride in water or $50\,g\,L^{-1}$ hydrated trisodium orthophosphate solution is often used because the conductivity is adequate. In some cases, chloride ions can inhibit dispersion and alkaline phosphates present more advantages. In general, the addition of an effective wetting agent or dispersant (directly to the sample, as explained above) greatly helps in dispersing the sample. The optimum choice of dispersant is often a matter of trial and error, with microscope examination being usual – particular attention should be paid to any eventual negative effects (such as dissolution). When the particulate material is sparingly soluble in water, the electrolyte should be first saturated with that material and filtered for usage. The saturated solution should not be left standing and the analysis should be performed immediately.

Alternatively, organic media (such as alcohols, ketones and chlorinated hydrocarbons) are needed for water-soluble materials, including salts, sugars, and foodstuff. Other materials may already be suspended in media that are immiscible with water. Polar organic liquids having dielectric constants greater than 10 with readily ionized materials such as lithium chloride or ammonium thiocyanate are widely used in both cases.

To measure small particles ($\leq 1\,\mu m$) with small apertures, the use of an electrolyte with a very high conductivity is recommended to increase the signal-to-noise ratio – a possible solution would be to use $60–80\,g\,L^{-1}$ sodium chloride in water instead of $10\,g\,L^{-1}$. However, problems may then be encountered in suspending large and/or dense particles that tend to settle in the dispersion beaker and/or in the tube behind the aperture. The addition of a thickening agent to increase the electrolyte viscosity (e.g. glycerol or sucrose) together with the use of a round-bottomed beaker fitted with baffles and special stirrer paddles favor the homogeneity of the suspension.[8]

For highly accurate particle-size analyses, electrolytes must be virtually free of particles. The electrolyte solutions should therefore be carefully filtered before use (0.45 μm or 0.22 μm membrane filters are commonly employed) and the background counting should not exceed the values recommended in the instrument manuals (see section 4.3).

As part of the normal operating procedure, a background count in clear electrolyte is always carried out and recorded, and later subtracted from the sample-plus-background data to obtain the true particle counts.

3.3 Orifice Tube Selection

Most distributions of particulate materials sized by electrical sensing have equivalent diameters in the range between 0.5 μm and 150–250 μm. Some commercial instruments are capable of measuring particles up to 1200 μm and experimental designs have provided results down to 0.1 μm.[18,33] However, broad size ranges can only be covered by using multiaperture analyses, as described later.

The effective size range that a typical orifice can measure is from about 2% to 60% of its orifice diameter, which corresponds to a size span of 30 : 1 by diameter. The lower limit is normally determined by the electrical noise which prevents the pulses generated by the smaller particles from being discernible. This noise may come from the electronic circuitry of the instrument, from surrounding equipment, or from particles in the sample that pass through the sensitive zone of the aperture without entering it. A special case may occur with sedimented particles that accumulate behind the aperture during analysis. They can be diagnosed by performing a background analysis after sample measurement without clearing the aperture tube.

The upper limit is essentially dictated by the aperture blockage which, for nonspherical particles, is mainly governed by their largest size, and by the increasing nonlinearity of the response (discussed above). There is experimental evidence that some models produce accurate measurements up to 70–80% of the aperture sizes.[21]

Determination of the largest and smallest particles present in the sample is usually made by microscope inspection, by trial-and-error procedure with various aperture tubes, or by some previous knowledge about the sample.

The apertures available span from 15 μm to 2000 μm. The use of the large apertures is controlled by the ability to suspend the particles uniformly in the beaker. Analyses with apertures less than 50 μm are more sensitive to noise and require special care with the experimental conditions – the strength and cleanliness of the electrolyte solution is crucial and any atmospheric contamination or electrical interference (internal or external) should be avoided as they can result in false counts.

Particles larger than recommended for a given aperture, or that tend to agglomerate, may cause aperture blockage. An aperture projection system, normally incorporated in the instrument, allows the operator to visualize any blockage or partial blockage. Blockages can also be detected by changes in the pulse pattern displayed on the oscilloscope, when available. In most cases, the blockages are readily cleared by backflushing or by brushing the particles off the orifice with a special brush (bent to a 90°

angle at the metal end and with the hairs cut short). However, certain analyzers have automatic blockage detection and clearance of the sensing orifice.[32]

Although the majority of materials encountered fall within a size range that can be analyzed using only one orifice, samples with a very wide size distribution require the use of two (or more) apertures. For example, over 2% by volume of the particles fall in the smallest size interval, if a bimodal size distribution with one mode essentially below the threshold is expected or if a significant mass-balance deficit is encountered, it is then advisable to use the multiaperture method[11] to obtain the full size distribution. The ratio of the orifice diameters should not exceed 5:1 to ensure that the ranges covered by each tube are allowed to overlap by several micrometers. In general, multitube operations require experienced operators and extra time because larger particles have to be removed by sieving or partial sedimentation, before using smaller aperture tubes. Furthermore, if the particle-size curves (number versus diameter) obtained with the two (or more) apertures do not overlap (due to incorrect calibration or loss of particles during separation), the procedure has to be repeated. Data blending can be performed manually or by software.

3.4 Data Processing

The capabilities of particle sizers have been immensely improved by increases in computer power and the ability to record and handle huge amounts of data in very short times has made virtually all measurements possible. The problem now is that instruments which measure the same particle property, and use essentially the same hardware, may give different results because of disparities in software.[3] This is a matter of concern for particle technologists who should be aware of how software packages manipulate the data. This is not so critical in stream counters, especially in electrozone sensing, because here there is no need for data deconvolution and the relationship between instrument response and particle size is well established.

Most commercially available instruments, based on the electrical sensing zone method, include a dedicated microprocessor or may be linked to a personal computer for data acquisition, storage, and processing. The analytical settings with which the data was obtained can also be saved, allowing easy retrieval for future analyses. Numerous options are now available to present the data in tabular form or graphically (cumulative or differential curves, undersize or oversize), using logarithmic or linear scales. The operator is able to select the presentation form and sequence for a particular report from a vast list of preferences.

Statistical analysis of the size distribution as a function of diameter, volume or surface area, including mean, median, mode, standard deviation, skewness, and kurtosis, is normally accessible. In some cases users can electronically isolate subpopulations of interest and further expand the measurement resolution.

Data saving also enables the plotting of multiple files on the same graph for comparative studies together with the corresponding statistics. Extrapolations to estimate the percentage below the detection limit may also be possible automatically, if neither a second aperture is used to complete the analysis nor a mass balance is performed (as explained later).

4 INSTRUMENT CALIBRATION AND VALIDATION

As the response of the electrical sensing zone method is essentially proportional to the volume of the particles, the pulse height provides a relative scale of particle volumes. Calibration involves converting the arbitrary pulse height into spherical diameter, that is, to determine the calibration constant, according to Equation (11)

$$K_{\mathrm{d}} = \frac{d}{\sqrt[3]{T}} \tag{11}$$

where K_{d} is the calibration constant based on diameter, d is the equivalent volume diameter, and T is the pulse height (threshold value).

Calibration can be performed in two different ways:

- Latex calibration – using narrowly distributed spherical latex particles.
- Self-calibration – utilizing the particles of the material under test.

Self-calibration, also called *mass calibration* or *mass integration*, is recommended in the British Standard[11] as a primary calibration procedure. It is superior to latex calibration because it eliminates any possible errors caused by shape, porosity or conductivity effects of the material to be analyzed. This procedure is therefore more direct and traceable; however, it is not used routinely, so it requires a more elaborate and consequently more time-consuming procedure. In addition, it must be ensured that all particles fall well within the size range of the aperture and no count losses occur in the instrument.

4.1 Latex Calibration

Latex calibration is commonly performed with latex samples which have certified modal, median and/or mean

sizes. Poly(styrene divinyl benzene) latices are particularly recommended for this purpose as these particles are durable and will not change size upon immersion in most electrolyte solutions (special precautions should be taken when using organic electrolytes because the latices may swell or dissolve in some of these liquids). The latex particles should have a mean diameter between 5% and 20% of the aperture diameter, and are obtainable from several sources including manufacturers of electrical sensing zone equipment.

In single-channel models, the calibration is often performed using the so-called half-count method.[34] This consists basically of determining the counts corresponding to threshold levels equal to $0.5T$ and $1.5T$, where T is the average height of the pulses visualized on the oscilloscope. The threshold value corresponding to the count which equals the average of the above counts is the one to be used in Equation (11) to evaluate the calibration constant (K_d), knowing the singlet number median diameter of the latex. More sophisticated particle counters, allowing multichannel analyses, can be more rapidly calibrated by relating the mode of the generated size distribution to the latex number mode.

The calibration constant, which is valid for each aperture tube–electrolyte pair, should be checked periodically and the results recorded to monitor any significant long-term deviation.

4.2 Self-calibration

Although latex calibration is more widely used, the most accurate method is self-calibration.[11,35,36] In this method, a size fraction of the material being examined, preferably not exceeding 10:1 by particle diameter, is diluted to an exactly known mass concentration in electrolyte solution. The volume of the particles in a metered volume of suspension V_p will be given by Equation (12)

$$V_p = \frac{V_m}{V_T}\frac{W}{\rho_s} \tag{12}$$

where V_m is the metered suspension volume, V_T is the total suspension volume, W is the total mass of the powder, and ρ_s is the particle density.

This volume can also be obtained by measuring the particle-size distribution, resulting in Equation (13):

$$V_p = \frac{\pi}{6}\sum \Delta n_i \overline{d}_i^3 \tag{13}$$

where Δn_i is the number of particles in a size interval i and $\overline{d}_i$ is the mean diameter (based on the mean volume) for that size interval.

Substituting Equation (11) in Equation (13) results in Equation (14),

$$V_p = \frac{\pi}{6}K_d^3\sum \Delta n_i \overline{T}_i \tag{14}$$

where $\overline{T}_i$ is the average threshold (corresponding to $\overline{d}_i$).

If all the particles have been counted over the whole measuring range, Equations (13) and (14) can be compared to give Equation (15):

$$K_d = \left(\frac{6}{\pi}\frac{V_m}{V_T}\frac{W}{\rho_s}\frac{1}{\sum \Delta n_i \overline{T}_i}\right)^{1/3} \tag{15}$$

This equation is often presented in the literature[11,34] in the alternative form (Equation 16)

$$K_d = \left(\frac{6}{\pi}\frac{V_m}{V_T}\frac{W}{\rho_s}\frac{1}{\sum \Delta n_i \overline{v}_i}\right)^{1/3} \tag{16}$$

where $\overline{v}_i$ is not always well defined and can be incorrectly identified with a real volume. Real volumes can only be obtained if a prior calibration has been performed. A more suitable form of Equation (16), in terms of volume values, has been proposed (Equation 17) as[37]

$$K_d = K_{d_0}\frac{V_m}{V_T}\frac{W}{\rho_s}\frac{1}{\sum \Delta n_i \overline{v}_{0,i}} \tag{17}$$

where K_{d_0} is the initial estimate of the calibration constant (which could be the latex calibration constant) and $\Delta n_i \overline{v}_{0,i}$ is the total volume of particles computed by the instrument when using K_{d_0}.

The difference between the particle-size distribution obtained by using the latex and the self-calibration constants were found to be negligible for moderately aspherical particles.[8,35,38] However, the self-calibration method is more fundamental and should be used to remove any doubt, especially when dealing with highly irregular, porous, or conductive particles, for which appreciable differences have been reported.[23,35,39–41] Self-calibration requires great accuracy in determining the particle concentration in the suspension and a counting efficiency of 100% in order to obtain a precise value for the measured volume. The chosen method of calibration should be specified when results are reported.

4.3 Instrument and Method Validation

The first check on instrument, aperture, and electrolyte occurs in the blank (background) measurement. Background counts should be lower than the values given in Table 2.

Table 2 Maximum acceptable background counts

Orifice diameter (μm)	Manometer volume (cm^3)	Maximum background count
280	2.0	75
200	2.0	200
140	0.5	150
100	0.5	400
70	0.5	1200
70	0.05	120
50	0.05	300
30	0.05	1500

The second check should come from the monitoring exercise of the calibration constant – the value of the calibration constant should lie within the limits for 95% confidence level relative to the predetermined mean values.[13]

Finally, a *mass-balance* procedure[10,11,42] is also recommended. This procedure is similar to that used for self- (or mass) calibration. Basically, it balances the volume of the particles measured by the instrument in a metered volume of suspension (Equations 13 or 14) with that calculated from the particle concentration (Equation 12). The ratio of these two values gives the fraction of the powder that is accounted for in the measurement. If there are no other particles present in the sample, there should be less than 3% deviation from 100%. Alternatively, this method may also be used to quantify the fraction of particles missed in the measurement, for example because their size is below the lower limit of the aperture. It is evident that the measurement results should be as precise and accurate as possible. Potential error sources and procedures to eliminate them have been discussed elsewhere.[42]

5 SPECIAL APPLICATIONS

Electrozone sensing, despite being a long-established and widely used method, is still the subject of study and development. Several approaches have been investigated to improve the resolution of electrozone sensors to measure closely sized particles. Increased interest in narrow and ultranarrow (coefficient of variation (CV) less than 2% for diameter) size-range materials, such as biological cells, polymer latices (used as size calibration references), and man-made monodisperse materials (for use as chromatography column packings), has demonstrated the need to improve the resolution of standard orifices. The signal produced when a particle passes through a conventional aperture depends on its size and other physical characteristics, and also on its path near and through the aperture, mainly due to the aperture electric field inhomogeneity.

As depicted in Figure 7, particles passing close to the edge of the orifice generate pulses somewhat higher and considerably longer (frequently M-shaped) than they should be, thus reducing the accuracy of the method. This does not affect the analysis of powders having a wide size distribution (as for most powders of industrial interest) but causes overestimated distributions of nearly monosized materials, which are typically skewed towards the coarser sizes and often present an additional peak.[24,43,44] The two procedures that have been suggested to improve this situation are electronic pulse editing (already discussed) and *hydrodynamic focusing*, where particles are directed along the central axis of the aperture.[45–47]

Hydrodynamic focusing (Figure 8) has been the most successful because it is straightforward, prevents particles from passing through regions of inhomogeneous electrical field and also eliminates circulation of particles close to the orifice (which normally results in countable pulses).

A system similar to hydrodynamic focusing has also been applied to measuring fibers (which are particles with a very low aspect ratio) using electrozone sensing.[48] Fiber measurement is of paramount importance in the pulp and paper industry, as fiber length and diameter relate directly to paper properties. The Kajaani FS-200,

Figure 7 Influence of particle flow path on pulse shape.

Figure 8 The hydrodynamic focusing principle.

an automated optical analyzer based on the ability of cellulosic fibers to change the direction of polarized light, has been extensively used for sizing pulp fibers.[49] More recently, improvements in computer-based image processing have also led to the development of fiber analyzers that provide rapid and operator-independent measurements.[50] All these automated analyzers comprise a configuration that allows fiber alignment in the measuring zone. As long as fibers flow axially through the aperture, it has been shown that if a prior calibration is performed with fibers of constant length, the instrument response is proportional to the fiber cross-sectional area, from which fiber diameter can be calculated. Fiber lengths can also be evaluated to some degree of accuracy by measuring the pulse duration instead of pulse amplitude.[8]

Other modifications relate to real-time analyses, that are not possible with the traditional off-line procedures and imply either on-line or in-line measurements.[3] The major difference between off-line and in-line measurement is that in the latter sampling and analyzing are closer both in time and space. In addition, on-line measurements reduce the sampling step even more by inserting a probe into the stream, thus allowing localized measurements. Although this increase in automation usually means a loss of accuracy, the benefits are considerable. For example, the data may be passed to a control program enabling process monitoring. It has been reported that electrozone sensors have been adapted for real-time processing.[51,52]

In the pharmaceutical industry electrozone analyzers are used not only to assess the drug particle size but also to study the disintegration of tablets, particle swelling, and dissolution rates[8,53–55] – the size of the drug particle determines its dissolution rate and, ultimately, the rate of absorption.

The limitations of the electrozone method mainly relate to particle characteristics. For example, particle porosity may influence the response of electrical sensing devices.[40,56,57] This is basically because when the pores get filled by the suspending medium they may not be counted as particle volume, resulting in measured volumes considerably smaller than the real particle envelope size. There are also some indications that the wetting properties of the electrolyte solution could also play an important role in the obtained data.[58] A number of researchers have investigated the effect of porosity by filling the pores with an inert material and have even suggested that the pore volume could be estimated from the differences in sizing raw and filled-pore samples.[40,56] However, by not assuming that the specific resistance of the particles (nonconductive as well as conductive) is practically infinite, it has been shown that the apparent resistance of some conductive particles (e.g. carbon, palladium, and nickel) are dependent on the voltage drop over the particle when it passes the orifice.[39,41,59] Critical values have been determined, above which particles may act as a conductor causing large deviations; therefore, adequate conditions must be established beforehand to ensure reliable measurements. Finally, there is evidence that the response of electrozone sensors, besides being a function of particle volume, is also affected by its shape.[8,21,23] Experiments carried out with large-scale versions of electrical sensing instruments indicated that shape has a constant effect which can be eliminated with self-calibration.[23]

6 COMMERCIAL EQUIPMENT

The majority of the electrical sensing zone-based instruments currently in use were manufactured by Coulter Electronics, and by Particle Data under the trade name of Elzone™. Coulter™ and Elzone™ are presently marketed by Beckman Coulter and by Micromeritics respectively. The most widely used models are the Coulter Model TAII, the Coulter ZM and the Elzone™ series 180.[10] Although many of these models are still in use, they are not in current production; the descriptions below are confined only to those models that are commercially available.

The Coulter models in current production are the Z series and the Coulter™ Multisizer IIe. The Z series was designed to be easy to use and consists of the Z1 single threshold, the Z1 dual threshold and the Z2. The Z1 is fundamentally a particle counter, whereas the Z2 is a particle counter and size analyzer that works in the 1–120 μm range. The latter records particle data in 64, 128, and 256 channels, enables the operator to view the data, allows statistical treatment of the results, and permits automatic run and an average of up to 10 replicates. The Coulter™ Multisizer operates in the overall size range 0.4–1200 μm at up to 5000 counts per second and also enables the selection of the number of size classes (channels), from 64 to 256. Built-in cursors permit the isolation of subpopulations, thus increasing the instrument resolution to 25 600 channels. Editing facilities are also available to remove the most distorted pulses which, as discussed before, improves the accuracy of the analysis of narrow-sized range materials. Dedicated personal computer software enables data processing and storage, size distribution statistics, run overlays and averages, multitube overlapping and data export (Figure 9).

At present, Micromeritics markets the Elzone™ 5380 and 5382 particle analyzers, both performing complete counting and sizing capability in the range 0.4–1200 μm. These analyzers are operated via an external personal

computer control module and both perform high-speed and multichannel analyses. The main difference between them is that the model 5380 (illustrated in Figure 10) has one analysis station whereas the 5382 has two. In addition, the latter has automated valves which highly reduce the operator intervention. A set of macro commands allows repetitive analyses and the software enables sample information and collected data to be saved which can be presented in tabular and graphic form and plot overlays. These models are capable of autoblockage detection and clearance at the sensing orifice.

Field-flow fractionation (FFF) is an analytical methodology suitable for the separation and characterization of macromolecules within a wide range of molar masses, and for particles in submicrometer and micrometer ranges. The separation is based on the action of effective physical or chemical forces across the separation channel. The field forces interact with the separated species and concentrate them at the appropriate position inside the channel. The resulting concentration gradient induces an opposite diffusion flux. This process leads to a quasi-steady-state distribution of the affected sample components across the channel. The velocity of the longitudinal flow of the carrier liquid also varies across the channel. A parabolic flow velocity profile is usually established inside the channel. The components of the separated sample are transported in the longitudinal direction inside the channel at different velocities, depending on the transverse positions of the zones of the sample components within the flow of the carrier liquid.

The separation is performed in one liquid phase. This is of fundamental importance for the fractionation and particle size analysis of biological samples, which can be sensitive to the type and intensity of the interaction with the surfaces and can denaturate. Steady-state inside the channel is usually reached within a short time due to a small channel thickness. The simplicity of the channel construction permits an accurate description of the separation processes.

The field strength can be controlled over a wide range. Many operational variables in FFF can be manipulated during the experiment by suitable programming.

Accurate analytical results can be obtained from FFF by correct treatment and interpretation of the experimental data. If the relationship between the retention parameters and the characteristics of the separated particles is known, or can be predetermined by using an appropriate calibration procedure, the characteristics of an unknown analyzed sample can be evaluated quantitatively. The particle size distribution (PSD) of the analyzed sample then is determined from a fractogram.

1 INTRODUCTION

FFF is relatively new but important analytical methodology suitable for the separation and characterization of macromolecules over a wide range of molar masses, starting at several thousand grams per mole up to perhaps $10^{18}\,g\,mol^{-1}$, and especially for particles in the submicrometer and micrometer ranges. Very few, if any, of today's separation techniques possess such flexibility. Its development since the late 1960s into a variety of specific methods and techniques represents an important contribution to the science and technology of analytical separations of large molecules and particles.

The separation in FFF is based on the action of effective physical or chemical forces (e.g. temperature gradient, electric, magnetic, gravitational, or centrifugal forces, chemical potential gradient, etc.) across the separation channel. The field forces interact with the separated species and concentrate them at the appropriate position inside the channel. The resulting concentration gradient induces an opposite diffusion flux. This process leads to a quasi-steady-state distribution of the affected sample components across the channel. The velocity of the longitudinal flow of the carrier liquid also varies across the channel. A parabolic flow velocity profile is usually established under conditions of laminar isothermal flow of a Newtonian liquid inside an imaginary channel composed of two parallel infinite planes or, in reality, in a channel of rectangular cross-section. As a result, the components of the separated sample are transported in the longitudinal direction inside the channel at different velocities

depending on the transverse positions of the zones of the sample components within the flow of the carrier liquid.

The general principle of FFF is demonstrated in Figure 1. A carrier liquid is pumped through the sample injector to the fractionation channel and leaves the separation system after passing through the detector, which allows the monitoring of the eluting species and the recording of the fractograms.

Two specific mechanisms – *polarization*[1] and *focusing*[2] – lead to the formation of different concentration distributions across the fractionation channel. The components of the fractionated sample are thereby differently compressed onto the accumulating wall of the channel, or focused at different positions, as shown by details (A) and (B) in Figure 1. Despite their principal differences, polarization and focusing FFF have many common characteristics such as the experimental procedures, instrumentation, data treatment, and the range of potential applications. The separation is performed in a single liquid phase. A stationary phase of large surface area (typical for a chromatographic column of comparable separation capacity) is absent in all FFF separation channels, regardless of the particular method or technique applied. This feature is of fundamental importance for the fractionation and particle size analysis of biological samples, which can be sensitive to the type and intensity of the interaction with the surfaces and can denaturate. The inner surface of the FFF channel plays no active role in the separation process and it can be deactivated so that undesirable interactions are minimized. Especially in focusing FFF methods, only a very small part of the separated species comes into direct contact with the channel walls. Steady-state inside the channel is usually reached within a short time due to a small channel thickness. The simplicity of the channel construction permits an accurate description of the separation processes.

Figure 1 The general principle and experimental arrangement of FFF: (1) carrier liquid reservoir, (2) pump, (3) injector, (4) separation channel, (5) external field, (6) hydrodynamic flow, (7) detector. The three-dimensional details of the channel section show (A) the polarization FFF mechanism and (B) the focusing FFF mechanism.

The strength of the field can be controlled over a wide range in order to manipulate the retention. Consequently, in polarization FFF methods, the complete passage of a particular sample component through the channel represents the lower retention limit, whereas the retention is total when the given component is completely compressed against the channel wall. Retention ratio, as defined by Equation (26), from zero to approximately 0.02 comes into account in practice for polarization FFF methods. With focusing FFF methods, the retention is even more versatile. Many operational variables in FFF can be manipulated during the experiment by a suitable programming, although not all have been applied experimentally.

Any displacement of the separated species depends on the existence of the driving forces. The processes which cause the formation of concentration gradients vary with the character of the field. Accordingly, the applied field determines the individual polarization FFF methods. However, the focusing process is always related to the existence of the gradient of the effective forces. Only when the driving forces are dependent on the position across the channel, and vanish at a given position, can focusing occur.

As a result, *polarization FFF* methods are classified with regard to the nature of the main field applied, whereas *focusing FFF* methods are classified by considering the combination of various gradients and fields, thereby emphasizing the focusing processes.

The historical background of this modern separation methodology can be seen, for example, in the recovery of gold by panning, or of other metals and minerals as demonstrated in the middle-ages rendition in Figure 2.[3] The gravitation and the stream of running water were used to separate the gold particles from other particulate material (soil, clay, sand, etc.). The use of this principle dates back to some 5000 years BC.

Some formerly proposed separation methods are also based on the combined action of field forces and hydrodynamic flow. The fractionation of proteins by combined electrophoresis-convection described by Kirkwood[4] in 1941 and extended in 1952 by Kirkwood and Brown[5] to a combination of diffusion-convection, or thermal diffusion combined with free thermal convection applied in Clusius and Dickel[6] thermogravitational columns, can be also considered as precursors of FFF.

Figure 2 Middle-ages device for the recovery of gold particles and minerals from sand, clay, and soil blends by combining sedimentation and quasihorizontal movement of water, accompanied by vigorous manual stirring of the mud cake.

However, the true beginnings of FFF can be attributed to Giddings[1] who described the general concept as well as polarization FFF. The aerostat shown in Figure 3, created by Joseph and Etienne Montgolfier,[7] is a phenomenological predecessor of the generic invention of the focusing FFF.[2] More specific or generalized separation mechanisms were subsequently proposed and exploited such as steric FFF[8] for the polarization FFF mode or generalized isoperichoric focusing FFF.[9,10] The term 'isoperichoric' was introduced by Kolin[11] and is derived from the Greek language where *isos* means 'equal' and *perichoron* means the 'environment'. This term therefore means that the focusing forces are generated by the difference between the local effective property of the dispersing carrier liquid and the corresponding parameter of the focused sample component.

Polarization FFF methods utilize the exponential concentration distribution that forms for each sample component across the channel, with the maximum

Figure 3 Aerostat of Montgolfier's brothers invention in 1783.

concentration at the accumulation wall. This is the consequence of the constant and position-independent velocity of the transverse migration of the affected species due to the field forces. This concentration distribution is combined with the velocity profile formed in the flowing liquid.

Focusing FFF methods make use of the transverse migration of each sample component under the effect of the driving forces that vary across the channel. As a result, the sample components are focused to positions where the intensity of the effective forces is zero and are transported longitudinally with different velocities according to the established flow velocity profile. The concentration distribution within a zone of a focused sample component can be described by Gaussian or similar distribution functions.

Accurate analytical results can be obtained from FFF by applying the correct treatment and interpretation of the experimental data. If the relationship between the retention parameters and the characteristics of the separated particles is known, or can be predetermined by using an appropriate calibration procedure, the characteristics of an unknown analyzed sample can be evaluated quantitatively. The PSD of the analyzed sample then is determined from a fractogram.

2 PRINCIPLES AND THEORY

The FFF methodology is based on the simultaneous action of the effective field forces and of the liquid flow inside a separation channel operating on the fractionated species. The channel thickness is small, usually between 50 and 500 μm; the ratio of the channel width to its thickness is typically between 20 and 200; the usual length is from 10 to 100 cm. The mutual orientation of the field forces and of the carrier liquid flow is perpendicular. The liquid flows in the direction of the channel longitudinal axis and the field forces act across the channel (Figure 1). The sample is injected into the channel as a short pulse or as a continuous stream carried by the flow. The field generates the driving forces which induce a mass flux of the sample components. A concentration gradient of each sample component is formed across the channel. This concentration gradient induces an opposite flux due to the diffusion, Brownian motion, repulsive interactions, etc. As a result, a steady-state concentration distribution of each sample component across the channel is established. Simultaneously, a flow velocity profile is formed across the separation channel. The sample components are transported in the direction of the flow at different velocities, depending on the position of the centers of gravity of their concentration distributions in the flow velocity profile. Consequently, they leave the channel at different elution times and are thus separated. Two distinct cases, A and B in Figure 1, correspond to the two different separation mechanisms, polarization and focusing, resulting in zones either differentially compressed at the accumulation wall or focused at different levels in a free volume of the channel. Although the separation and accompanying processes are carried out in a three-dimensional channel, the following two-dimensional model is a fair approximation of the reality.

The driving forces can be generated by a single field as well as by the coupled action of two or more different fields. Polarizing and focusing forces can operate simultaneously, resulting in a complex mechanism of separation. The field force, F, and consequently the migration velocity, U, are independent of the position in the direction of the x axis in polarization FFF (Equation 1):

$$F \neq 0 \text{ and } U \neq 0 \text{ for } 0 < x < w \tag{1}$$

Here w is the distance between the main channel walls in the direction of the x axis, with $x = 0$ at one wall of the channel. Dispersion processes act against field induced flux until the steady state is reached. The steady-state concentration distributions of the affected sample components across the channel are exponential only if ideal polarization FFF is effective.

However, it holds for the x axis-dependent direction of the field force in focusing FFF (Equations 2–5):

$$F = F(x) \text{ and } U = U(x) \quad \text{within } 0 < x < w \tag{2}$$

$$F(x) = 0 \text{ and } U(x) = 0 \text{ for } x = x_{\max} \quad \text{with } 0 < x_{\max} < w \tag{3}$$

$$F(x) > 0 \text{ and } U(x) > 0 \quad \text{for } x < x_{\max} \tag{4}$$

$$F(x) < 0 \text{ and } U(x) < 0 \quad \text{for } x > x_{\max} \tag{5}$$

Here the coordinate $x_{\max}$ corresponds to the position at which the concentration distribution of a sample component across the channel attains its maximal value. Each sample component is focused in the direction of the x axis around its proper $x_{\max}$ position. The dispersive forces, in this case, act in both opposite directions from the $x_{\max}$ position until the steady state is reached. The resulting shape of the concentration distribution is close to the Gaussian distribution function.

Selective transport of the separated sample components and related dispersion phenomena are the main processes that characterize any separation method. A sample component undergoing the effect of the field forces in FFF is displaced in the moving carrier liquid by the combined action of the flow and field applied. The resulting velocity vector $\mathbf{u}$ can be decomposed into two perpendicular vectors: $\mathbf{U}$, induced by the applied field, and a flow-induced

component **v** (Equation 6).

$$\mathbf{u} = \mathbf{U} + \mathbf{v} \tag{6}$$

The total flux of a sample component **j** can also be written as a sum of transversal flux in the direction of the x axis and of axial flux in the direction of the longitudinal y axis (Equations 7–9):

$$\mathbf{j} = \mathbf{j}_x + \mathbf{j}_y \tag{7}$$

$$\mathbf{j}_x = -D_x \mathbf{r}_x \frac{\partial c}{\partial x} + \mathbf{U}c \tag{8}$$

$$\mathbf{j}_y = -D_y \mathbf{r}_y \frac{\partial c}{\partial y} + \mathbf{v}c \tag{9}$$

where $D_{x,y}$ and $\mathbf{r}_{x,y}$ are the diffusion coefficients and the unit vectors, respectively, and c is the concentration.

The transverse and longitudinal transports can be considered separately, in a first approximation. However, the longitudinal flow of the carrier liquid permanently perturbs the transverse concentration distribution. The deviation from the steady-state can be characterized by the equilibrium departure term ε (Equation 10):

$$c = c^*(1 + \varepsilon) \tag{10}$$

where c and c^* are the actual and steady-state concentration distributions, respectively.

2.1 Polarization Mechanism

The polarization mechanism is characterized by the transversal flux at equilibrium (Equation 11).

$$D_x \mathbf{r}_x \frac{\partial c}{\partial x} - \mathbf{U}c = 0 \tag{11}$$

The solution of Equation (11) is the exponential concentration distribution of the sample component across the channel (Equation 12):

$$c(x) = c(0) \exp\left(\frac{\mathbf{r}_x \mathbf{U}}{D}\right. \tag{12}$$

With respect to the positive direction of the x axis, the vector **U** is negative. Consequently, Equation (11) can be rewritten in the form of Equation (13):

$$-D_x \frac{\partial c}{\partial x} - Uc = 0 \tag{13}$$

As a result, Equation (12) can be rewritten in scalar form as (Equation 14):

$$c(x) = c(0) \exp\left(\frac{-xU}{D}\right. \tag{14}$$

Defining the mean layer thickness as $l = D/U$ gives Equation (15):

$$c(x) = c(0) \exp\left(\frac{-x}{l}\right. \tag{15}$$

For strongly polarized concentration distributions, the mean layer thickness measured from the accumulation wall, is practically equal to the position of the center of gravity of the concentration distribution in the direction of the x axis.

2.2 Focusing Mechanism

The flux of a sample component in the direction of the x axis is expressed by Equation (16):

$$\mathbf{j}_x = -D_x \mathbf{r}_x \frac{\partial c}{\partial x} + \mathbf{U}(x)c \tag{16}$$

Equation (16) differs from Equation (8) by the x axis-dependent velocity $\mathbf{U}(x)$. At the steady state Equation (17) holds:

$$D_x \mathbf{r}_x \frac{\partial c}{\partial x} - \mathbf{U}(x)c = 0 \tag{17}$$

The velocity vector $\mathbf{U}(x)$ is either positive or negative regarding the orientation of the x axis and relative to $x_{\max}$. The force $F(x)$, acting on one particle undergoing the focusing can be written in scalar form as Equation (18):

$$F(x) = U(x)f \tag{18}$$

The friction coefficient is defined by Equation (19):

$$f = \frac{kT}{D} \tag{19}$$

where k is the Boltzmann constant, T is the absolute temperature, and D is the diffusion coefficient. Then Equation (20) holds:

$$\frac{\mathrm{d}c}{\mathrm{d}x} = -\frac{F(x)c}{kT} \tag{20}$$

The focusing force can be approximated by Equation (21):

$$F(x) = \left(\frac{\mathrm{d}F(x)}{\mathrm{d}x}\right._{x \approx x_{\max}} (x - x_{\max}) \tag{21}$$

where $(\mathrm{d}F(x)/\mathrm{d}x)_{x \approx x_{\max}}$ is the driving force gradient, assumed constant near $x_{\max}$. The solution of Equation (20) is given by Equation (22),

$$c(x) = c_{\max} \exp\ -\frac{1}{2kT} \left(\frac{\mathrm{d}F(x)}{\mathrm{d}x}\right._{x \approx x_{\max}} (x - x_{\max})^2 \tag{22}$$

which is the Gaussian concentration profile of a single focused component.

A completely different approach,[12,13] which takes into account the actual shape of the transverse gradient of the focusing forces, leads to accurate solution without an a priori assumption of the constancy of the gradient in the domain of the focused zone. The details are given in the section on focusing methods and techniques.

2.3 Flow Velocity Profiles

The separation is performed inside a narrow channel, usually composed of two highly polished plane and parallel surfaces between which a spacer of given constant thickness is clamped. Such a design results in a rectangular cross-section channel. Other shapes of the channel cross-section result in different hydrodynamic conditions and various flow velocity profiles. Velocity distribution in the isothermal, isoviscous flow of a Newtonian carrier liquid flowing between two parallel infinite planes under laminar conditions and not affected by a field is parabolic and described by Equation (23),

$$v(x) = \frac{\Delta P x(w - x)}{2L\mu} \tag{23}$$

where $v(x)$ is the longitudinal velocity at the x coordinate, ΔP is the pressure drop along the channel of length L, and μ is the viscosity of the carrier liquid. It holds for the average velocity (Equation 24):

$$\langle v(x) \rangle = \frac{\Delta P w^2}{12L\mu} \tag{24}$$

which is obtained by integration of Equation (23) over the whole thickness of the channel. An axially symmetric parabolic flow velocity profile is the most frequent case found in practice. However, it might be advantageous to construct a channel in which an axially asymmetrical flow velocity profile is formed. This interesting possibility is discussed in sections dealing with specific FFF methods and techniques.

2.4 Convolution of Transverse Concentration and Flow Nonuniformities

Separated species undergo two fundamental transport processes, transverse flow caused by the imposed field and longitudinal hydrodynamic flow. The separation is due to interference of the established concentration and flow nonhomogeneities. Whenever the exponential concentration distribution across the channel of each sample component is established under static conditions without hydrodynamic flow, the zones of all components are superimposed. Only under dynamic conditions, with the liquid flow applied, can separation of the individual zones occur. The sample components are transported in the direction of the longitudinal axis of the channel at different velocities, that depend on the distance of their centers of gravity from the channel accumulation wall. Larger species are usually compressed closer to the accumulation wall and, consequently, the elution order is from the smallest particles to the largest ones. Polarization FFF usually exploits constant driving forces; however, this can be varied during elution by programming.

Two limiting cases in polarization FFF are related to the intensity of the field forces. When this intensity is zero, the transverse flux of the separated species may occur under laminar flow conditions due to the shear forces. As a result, axial separation may occur as in hydrodynamic chromatography.[14] If the driving forces are strong enough to concentrate all components as close as possible to the accumulation wall, the mean distance of Brownian motion is lower than any component radius and the mean distance of the species from the accumulation wall is equal to their radius. Consequently, larger species migrate into streamlines of higher velocities than smaller ones, and are eluted more rapidly. In principle, any effective field may be applied to this steric mode of FFF (Figure 4).[8]

The situation is quite different for the convolution of Gaussian concentration distribution of the separated sample components appearing in focusing FFF with an axially symmetrical flow velocity profile. In this case, partial or complete separation can occur of the individual zones of some or all sample components in the (x axis) direction of the field. The resolution already achieved by focusing should not be degraded by the additional hydrodynamic transport in the longitudinal direction. It is evident, that if some of the zones are focused at the same but opposite distances from the central longitudinal axis of the channel, they are transported by the flow at identical velocities. Therefore, no longitudinal separation occurs even when the focused zones are well separated in the direction of the focusing field action. A convenient solution is to exploit only one half of the channel or to establish the conditions under which the asymmetrical flow velocity profile is formed. In such a case, the combination of the axially asymmetrical

Figure 4 Principle of steric FFF. All sample components are in contact with the accumulation wall as a result of the high intensity of the applied field. As a result, steric hindrance causes larger particles to be eluted more rapidly than the smaller ones.

flow velocity profile with the Gaussian concentration distribution has the advantage that quasitotal volume of the channel can be used for the separation. It is demonstrated below that an important increase in the resolution of the focused zones can be achieved under dynamic conditions in comparison with the resolution obtained in the direction of the focusing processes under static conditions. This was an important finding, which demonstrated theoretically and experimentally the major advantage of dynamic focusing FFF over classical focusing separations performed under static conditions.[15]

2.5 Retention

Retention relates the elution velocity of the sample component in question with the average velocity of the carrier liquid. The average velocity of the zone migration of a retained sample component in the direction along the channel is given by Equation (25),

$$v_{\mathrm{r,ave}} = \frac{\langle c^*(x)v(x)\rangle}{\langle c^*(x)\rangle} \tag{25}$$

where the angle brackets denote average values. The retention ratio R is defined as the average velocity of a retained sample component to the average velocity of the carrier liquid which is equal to the average velocity of an unretained sample component (Equation 26):

$$R = \frac{v_{\mathrm{r,ave}}}{\langle v(x)\rangle} \tag{26}$$

The integral form of Equation (26) is Equation (27):

$$R = \frac{\int_0^w c(x)v(x)\,\mathrm{d}x \Big/ \int_0^w \mathrm{d}x}{\int_0^w c(x)\,\mathrm{d}x \Big/ \int_0^w v(x)\,\mathrm{d}x} \tag{27}$$

where $v(x)$, $c(x)$ are the local velocity and concentration, respectively, of the retained species. Both vary as a function of the transverse position in the direction of the x axis. The calculation of the retention ratio R gives different relationships for various concentration distributions of the retained species, corresponding to either polarization or focusing mechanisms, and various symmetrical or asymmetrical flow velocity profiles. From the practical point of view, the retention ratio R can be expressed as the ratio of the experimental retention time t_0 or the retention volume V_0 of an unretained sample component to the retention time t_{r} or the retention volume V_{r} of the retained sample component (Equation 28).

$$R = \frac{t_0}{t_{\mathrm{r}}} = \frac{V_0}{V_{\mathrm{r}}} \tag{28}$$

The retention volume of the unretained sample component should be equal to the void volume of the fractionation channel. The deviations from this ideal case can be caused by flow imperfections inside the channel and by extrachannel elements of the separation system. However, they are usually negligible for a carefully built separation system.

FFF is often performed in channels of simple geometry, which assists in establishing a rigorous analytical relationship between the retention ratio and the position of the center of gravity of the concentration distribution in the direction of the x axis. As in many cases, a known relationship between the position of the center of gravity of the zone and the molecular parameters of the sample component exists, the size parameters can be calculated from the experimental retention data without the need for a calibration procedure.

2.6 Retention Ratio in Polarization Field-flow Fractionation

Substitution for $c(x)$ and $v(x)$ in Equation (27) and integration give Equation (29):

$$R = 6\lambda\left(\coth\left(\frac{1}{2\lambda}\right. \right. \quad - 2\lambda \tag{29}$$

where $\lambda = l/w$. This equation is the basic relationship for the retention in polarization FFF performed in an ideal channel composed of two parallel and infinite planes.[16] If λ is small, $\coth(1/2\lambda)$ approaches unity and the approximation of Equation (30) holds:

$$\lim_{\lambda\to 0} R = 6(\lambda - 2\lambda^2) \tag{30}$$

Thus, for very small λ, Equation (31) is true:

$$\lim_{\lambda\to 0} R = 6\lambda \tag{31}$$

The graphical representations of Equations (29) to (31) are given in Figure 5. The retention ratio R can theoretically reach values from 1 (for an unretained sample component) to 0 (for a totally retained sample component). It can be seen that the above approximations are acceptable within the range of common experimental errors for $R < 0.25$.

Equation (29) cannot be used to calculate λ directly from the experimental retention ratio. A numerical iteration procedure must be applied. Equation (30) represents a good first iteration step in a computer iteration procedure. The physical meaning of λ can be best understood by taking into account that the force of the friction counteracting the movement of the particle due to the applied field is proportional to the product of the

Figure 5 Dependence of the retention ratio R on the retention parameter λ calculated from rigorous and approximate relationships for polarization FFF.

velocity U and of the friction coefficient f (Equation 32):

$$= fU \tag{32}$$

At the steady state, the force of the friction is equal to the force acting on a sample component due to the effective field. Equation (33) holds for the friction coefficient:

$$f = \frac{\mathcal{R}T}{D} \tag{33}$$

where $\mathcal{R}$ is the gas constant and is Avogadro's number. Thus the velocity of the particle migration in the direction of the field action is determined by the ratio of the effective field force to the friction coefficient (Equation 34):

$$\lambda = \frac{kT}{Fw} \quad \text{or} \quad \lambda = \frac{\mathcal{R}T}{Fw} \tag{34}$$

The parameter λ is then the ratio of the thermal energy to the effect of the field on one particle. The above relationships enable evaluation of the size characteristics of the retained sample components from the experimental retention data. Whenever a straightforward relationship between the retention parameter λ and the size of the retained sample component exists, the size can be directly calculated from experimentally determined R values. Nevertheless, even in those cases when the relationship between λ and the size of the separated sample component is not known, it can be established by a convenient calibration procedure.

Most channels used for polarization FFF are constructed with a rectangular cross-section having a large width to thickness ratio that approaches an ideal two-infinite-parallel-planes configuration. In a few cases, a cylindrical capillary tube has been used as an FFF channel, so that the circular symmetry with respect to the central longitudinal axis has to be taken into account. The two distinct situations that can occur under these conditions are shown in Figure 6. In the first case the field-induced transport of the separated particles is generated in the radial direction from the central longitudinal axis of the cylindrical channel to the wall. The resulting radial concentration distribution is circularly homogeneous. This situation occurs when, for example, a semipermeable wall allows a radial uniform flow of a liquid due to the pressure difference between the interior and exterior of the cylindrical capillary, but retains larger size particles. The second situation is with an external field applied across the circular cross-section capillary.

Figure 6 (a) Axially symmetric exponential concentration distribution and (b) axially asymmetric exponential concentration distribution formed in a cylindrical FFF channel.

An axially asymmetric flow velocity profile can be formed in a cross-sectional permeability separation channel whose cross-section is not rectangular but, for example, trapezoidal. This type of channel can exhibit important advantages when used for focusing FFF.[17]

However, the convolution of an axially asymmetrical flow velocity profile with an exponential concentration distribution does not improve the separation. This is because the central part of the velocity profile is often quasiparabolic, which is not advantageous when compared to a parabolic symmetrical flow velocity profile.

2.6.1 Steric Exclusion

In some cases, the size of the separated particles can be commensurable with the thickness of the channel, and the steric exclusion mechanism must be taken into account (namely in polarization FFF; Figure 4). The particles carried by the liquid flow are in permanent contact with the accumulation wall. Consequently, their size is crucial for the velocity of their longitudinal transport – larger particles move ahead of smaller ones. The limiting relationship for the retention ratio in steric FFF is given by Equation (35),[8]

$$\lim_{\alpha \to 0} R = 6\alpha \tag{35}$$

where $\alpha = r/w$, r being the particle radius. If both polarization and steric FFF participate on the separation, the limit value of R is given by Equation (36):

$$\lim_{\alpha,\lambda \to 0} R = 6\alpha + 6\lambda \tag{36}$$

More details on this mechanism can be found in the section on sedimentation FFF.

2.7 Retention Ratio in Focusing Field-flow Fractionation

General retention theory for focusing FFF[18] has been developed for basic shapes of fractionation channel cross-section, starting from the idea of sedimentation-flotation focusing field-flow fractionation (SFFFFF).[2] As mentioned above, the use of an axially symmetrical (e.g. parabolic) flow velocity profile results in being unable to separate two focused zones with the same, but opposite, distances from the central axis of the channel. To avoid this problem, it is possible to use only one half of the channel between one wall and the central axis, or to divide the channel at the end by a longitudinal splitting to conduct each half of the carrier liquid via a separate output. However, it is then necessary to use two independent detectors and this might be an experimental difficulty for analytical applications. Another solution is to form an axially asymmetrical flow velocity profile in the plane of the focused zones. These possibilities represent a challenge for fundamental methodological research, and have not been developed to a level suitable for analytical applications. Consequently only the simplest relationship, describing retention in infinite parallel planes geometry or in rectangular cross-section channels, for which the ratio of the channel width to its thickness is large enough, is given here.

The retention ratio R can be calculated by substituting from Equations (22) and (23) into Equation (27) and by integration. The approximate solution for infinite parallel planes configuration or for rectangular cross-section channel is (Equation 37)

$$R = 6(\Gamma_{\max} - \Gamma_{\max}^2) \tag{37}$$

where $\Gamma_{\max} = x_{\max}/w$ is the dimensionless coordinate of the maximal concentration of the focused zone. Numerical calculations have confirmed that Equation (37) represents a good approximation of the exact solution[18] provided that the focused zone is narrow. Relationships for retention in channels of other than rectangular cross-section can be found elsewhere.[15]

2.8 Zone Dispersion

Any separation process is accompanied by zone broadening due to the spreading processes that have a tendency to disperse the concentration distribution already achieved by separation. The efficiency of the separation increases with decreasing proportion of these dispersive processes. A conventional parameter that describes quantitatively the efficiency of any separation system is the height equivalent to a theoretical plate H (Equation 38):

$$H = L\left(\frac{\sigma}{V_r}\right)^2 \tag{38}$$

where V_r is the retention volume and σ is the standard deviation of the elution curve of a sample component. The width of the elution curve described by the standard deviation reflects several contributions to the zone broadening: longitudinal diffusion; nonequilibrium and relaxation processes; spreading due to the external parts of the whole separation system, such as the injector, detector, connecting capillaries, etc. A graphical representation of these contributions as a function of the average linear velocity of the carrier liquid is shown in Figure 7. The sum of all contributions results in a curve which exhibits a minimum. As the diffusion coefficients of the particles are very low, the longitudinal diffusion is practically negligible and the optimal efficiency (the minimum on the resulting curve) is at a very low flow velocity. Instrumental and relaxation spreading can be minimized by optimizing the experimental conditions. From the practical point of view, whenever the zone dispersion cannot be suppressed enough by optimization of the experimental conditions, then correction of the fractograms for zone broadening must be applied. These correction procedures are discussed below.

Figure 7 Dependence of the efficiency of FFF, expressed as the height equivalent to a theoretical plate H on the average linear velocity of the carrier liquid $\langle v(x)\rangle$, demonstrating various contributions to the total H.

2.8.1 Relaxation

An important contribution to zone broadening is from relaxation processes, but it can be reduced by a convenient experimental procedure. The concentration distribution of the fractionated sample across the channel immediately after the injection is far from equilibrium; the steady state is established progressively. If the flow is stopped after injection for a time necessary for the relaxation, the shift of the retention volume and the zone spreading can be suppressed.[19] It is even possible to continue the elution with a higher velocity after a stop-flow period without losing the efficiency and resolution. The effect of this relaxation on the height equivalent to a theoretical plate, and retention and its suppression by the stop-flow procedure, is demonstrated in Figure 8.[19]

If the intensity of the field varies during the elution (e.g. by programming), the additional, secondary relaxation processes occur. However, deviation from the steady state is minor if the variation of the field intensity is slow enough.

Figure 8 Effect of stop-flow time on the retention ratio R and the efficiency H.

2.9 Particle Size Distributions

Most of real particulate samples are not uniform in size but exhibit a heterogeneity (polydispersity) that can be described by a distribution function. The PSD function, or simply the PSD, is a numerical or graphical representation of the relative proportion of each particle size composing the whole analyzed sample. A minimal particle size difference in a polydisperse sample is given by an increment which corresponds to a construction unit of the particles in question. The increment can be a molecule of a given size, the monomer unit if the particle is a polymer, or the aggregate of many molecules, etc. As a result, each PSD has a discrete character. This is demonstrated in Figure 9 where the PSD of a model sample is composed of particles of six different diameters, d_1 to d_6. The heights h_i represent the corresponding amounts of the particles of the diameter d_i (e.g. h_2 for the particle of the diameter d_2). This amount can be expressed as the number of particles of a given diameter relative to the number of all particles in the sample (Equation 39),

$$N_i = \frac{n_i}{\sum_0^\infty n_i} \tag{39}$$

or as the mass of the particles of a given diameter relative to the total mass of the sample (Equation 40),

$$M_i = \frac{m_i}{\sum_0^\infty m_i} \tag{40}$$

Accordingly, the PSDs are called number or mass PSDs.

A separation method such as FFF provides the experimental data (a fractogram) that can be treated in order to obtain the required true PSD. The PSD can

Figure 9 PSD of a model sample composed of six different particle diameters.

be used further to calculate various average particle sizes, polydispersity indexes (e.g. the standard deviation), and higher statistical parameters of the distribution function which represent a quantitative numerical information about the shape (asymmetry, etc.) of the experimentally measured PSD.

The increment between two closest particle sizes is usually too small to be distinguished by any separation method. The resulting fractogram is therefore a superposition of the individual particle sizes, and the physically discrete PSD is approximated by a continuous distribution function as shown graphically in Figure 9. The approximation can be performed by using standard methods of nonlinear regression. The raw experimental PSDs are very often and successfully approximated either by a continuous Gaussian distribution function, as defined by Equations (41) and (42), or less frequently by a discrete distribution, such as a Poisson distribution as defined by Equations (43) and (44).

The unnormalized Gaussian (differential) mass distribution function is

$$M(d_i) = \frac{\exp[-(d_i - d_{\max})^2/2\sigma^2]}{(2\pi\sigma^2)^{1/2}} \tag{41}$$

and the corresponding unnormalized Gaussian number distribution function is

$$N(d_i) = \frac{6}{\pi d_i^3 \rho_i} \frac{\exp[-(d_i - d_{\max})^2/2\sigma^2]}{(2\pi\sigma^2)^{1/2}} \tag{42}$$

The unnormalized discrete Poisson (differential) number distribution function is

$$N(P-1) = \frac{\exp(-r) r^{(P-1)}}{(P-1)!} \quad \text{with} \quad P = 1, 2, 3, \ldots \tag{43}$$

which can be easily converted into mass distribution function

$$M(P) = \frac{P \times N(P)}{\sum_0^\infty P \times N(P)} \tag{44}$$

The PSD can take the form of a differential distribution or a cumulative (integral) distribution. If the detector response is proportional to the mass of the particles, the differential mass distribution function $M(d_i)$ can be converted into integral mass distribution function $I(d_i)$ by Equation (45):

$$I_m(d_i) = \int_0^\infty M(d_i)\, \mathrm{d}d_i \tag{45}$$

Analogically, for integral number distribution function (Equation 46):

$$I_n(d_i) = \int_0^\infty N(d_i)\, \mathrm{d}d_i \tag{46}$$

Figure 10 Model Gaussian differential and integral distribution functions.

Figure 11 Model Poisson differential and integral distribution functions.

Graphical representations of the model Gaussian and Poisson differential and integral distribution functions are given in Figures 10 and 11.

2.9.1 Average Particle Sizes and Polydispersities

In addition to the PSDs, it is useful to be able to calculate various average particle sizes and polydispersity indexes. If the detector response is proportional to the mass of the particles (as already suggested above), which is the most frequent case in usual detection systems, the mass average particle diameter can be calculated from the fractogram by using Equation (47):

$$\overline{d}_m = \frac{\sum_0^\infty m_i d_i}{\sum_0^\infty m_i} = \frac{\sum_0^\infty h_i d_i}{\sum_0^\infty h_i} \tag{47}$$

The number average particle diameter can be calculated from the same fractogram by using Equation (48), provided that the density ρ_i is constant and independent of the particle diameter:

$$\overline{d}_n = \frac{\sum_0^\infty n_i d_i}{\sum_0^\infty n_i} = \frac{\sum_0^\infty h_i}{\sum_0^\infty h_i/d_i} \tag{48}$$

because Equation (49) holds true:

$$n_i = \frac{h_i}{m_i} = \frac{6h_i}{\pi \rho_i d_i^3} \tag{49}$$

The polydispersity (the width of the distribution curve) can be conveniently and most simply characterized by the index of polydispersity (Equation 50):

$$I = \frac{\overline{d}_m}{\overline{d}_n} \tag{50}$$

Another possibility is to calculate the standard deviation σ of the PSD from the fractogram, defined by Equation (51):

$$\sigma = \left[\frac{\sum_0^\infty (d_i - \overline{d}_n)^2 h_i}{\sum_0^\infty h_i} \right]^{1/2} \tag{51}$$

A graphical representation of the meaning of standard deviation of a model fractogram is given in Figure 12.

All above-mentioned PSD characteristics are derived from the defined statistical moments μ and central statistical moments relative to zero μ_0 of the jth order of a general distribution function $F(x)$ (Equations 52 and 53):

$$\mu_j = \frac{\int_{-\infty}^{+\infty} x^j F(x)\,\mathrm{d}x}{\int_{-\infty}^{+\infty} F(x)\,\mathrm{d}x} \tag{52}$$

$$\mu_{0,j} = \frac{\int_{-\infty}^{+\infty} (x - \mu_1)^j F(x)\,\mathrm{d}x}{\int_{-\infty}^{+\infty} F(x)\,\mathrm{d}x} \tag{53}$$

where Equation (54) must be satisfied for the normalized moments:

$$\int_{-\infty}^{+\infty} F(x)\,\mathrm{d}x = 1 \tag{54}$$

2.9.2 *Correction of Particle Size Distribution for Zone Broadening*

Section 2.8 demonstrated that a zone corresponding to a separation of a uniform particulate species is broadened due to dispersive processes. Consequently, the resulting fractogram of a polydisperse sample is a superposition of two processes: separation of discrete size particles and zone broadening. This is shown in Figure 13 where five different particle size fractions elute at different elution volumes, in which their zones are spread and overlapped, and the resulting fractogram is a convolution of all individual zones. The apparent PSD, calculated directly from such a raw experimental fractogram by using the above relationships, is broader than the true one.

To obtain an accurate PSD, corresponding average particle sizes, and polydispersity indexes, a correction procedure for the zone broadening should be used. An efficient correction method, applicable to FFF, was described by Jáhnová et al.[20] This method was derived from more general correction procedures, currently used

Figure 12 Graphical evaluation of the standard deviation σ from a fractogram. The distance between the sections of the tangents at inflection points with the baseline determines 4σ.

Figure 13 The fractogram of a sample of discrete PSDs is a superposition of the spread of zones of the individual discrete size species.

in size exlusion chromatography of polymers.[21] It is based on the above idea that a real experimental fractogram $h(V)$ of a polydisperse particulate sample is a convolution of two distribution functions, namely the fractogram corrected for zone broadening and which corresponds to the true PSD $g(Y)$, and the spreading function $G(V,Y)$ that represents the normalized detector response to a uniform particulate fraction having the elution volume Y (Equation 55):

$$h(V) = \int_0^\infty g(Y)G(V,Y)\,\mathrm{d}Y \tag{55}$$

where V and Y are then the elution volumes. Equation (55), called Tung integral equation, is the basis for all well-known correction methods.[21] It can be solved analytically only under certain conditions. It is, above all, the requirement of a uniform spreading function. In such a case, it becomes a convolution integral (Equation 56):

$$h(V) = \int_0^\infty g(Y)G(V - Y)\,\mathrm{d}Y \tag{56}$$

In a number of practical cases, the spreading function can be approximated by the normal Gaussian function (Equation 57):

$$G = \left(\frac{1}{2\pi\sigma_s^2}\right)^{1/2} \exp\left(\frac{-(V-Y)^2}{2\sigma_s^2}\right) \tag{57}$$

where σ_s is the standard deviation of the spreading function which is assumed to be independent of the elution volume. As this independence is valid in FFF only for a restricted range of elution volumes, Equation (57) can only be applied to fractograms of samples with a narrow PSD. However, if a nonuniform spreading function is used, the correction procedure can be applied to samples exhibiting wider PSDs (Equation 58):

$$h(V) = \int_0^\infty \left(g(Y)\frac{1}{2\pi\sigma_s^2(Y)}\right)^{1/2} \exp\left(\frac{-(V-Y)^2}{2\sigma_s^2(Y)}\right)\,\mathrm{d}Y \tag{58}$$

This function can be numerically solved. A graphical representation of a model result of the application of correction procedure is shown in Figure 14.

A practical application of the above-described treatment of an experimental fractogram is demonstrated by the real fractogram of a polymer latex obtained from sedimentation FFF, reproduced in Figure 15. The flowchart of the correction program is shown in Figure 16, and the resulting corrected PSD is compared with the uncorrected one in Figure 17.

Some authors have confirmed and extended the treatment of raw FFF experimental fractograms in order to correct the PSD for zone broadening.[22–24]

Figure 14 Effect of applying a zone-spreading correction to an uncorrected fractogram.

Figure 15 Treatment of an experimental sedimentation FFF fractogram of a polymer latex.

2.9.3 Practical Data Treatment

In following sections, the dependences of the retention ratio R on the diameter of the fractionated particles are discussed for various polarization FFF methods. If such a dependence is not linear but the segmentation of the experimental fractogram is regular (i.e. that ΔV_i between the h_i values is constant), the increment of the particle diameter Δd_i varies with corresponding h_i values. This fact must be taken into account in the experimental data treatment in order to obtain the accurate results.[25] The equations that follow give accurate relationships concerning various transformations of the integral to differential distributions and vice versa, and conversions of the raw experimental fractograms into PSDs. The differential mass PSD can be calculated by differentiating the integral PSD (or cumulative fractogram) according to Equation (59):

$$M(d_p) = -\frac{\mathrm{d}I(d_p)}{\mathrm{d}d_p} = -\frac{\mathrm{d}I(V)}{\mathrm{d}V}\frac{\mathrm{d}V}{\mathrm{d}V(d_p)}\frac{\mathrm{d}V(d_p)}{\mathrm{d}d_p} \tag{59}$$

Figure 16 Flowchart of a program to correct for zone spreading.

Figure 17 Effect of the correction procedure on two real fractograms. The difference between the corrected and uncorrected fractograms is very important for a fractogram obtained by (a) high-speed sedimentation FFF where the broadening of the zone due to the nonequilibrium processes cannot be neglected. (b) The difference between the corrected and uncorrected fractograms is minimal for a fractogram obtained by sedimentation FFF at reduced flow-rate where the broadening of the zone is lower. The correction for zone spreading need not necessarily be applied.

The cumulative particle mass values are calculated from Equation (60),

$$I(V) = \frac{1}{A_T} \sum_i A_i(V_i) \tag{60}$$

where A_T is the total area of the fractogram. If needed, the differential number PSD can be deduced from mass PSD by Equation (61):

$$N(d_p) = \frac{M(d_p)}{d_p} = \frac{h_i}{\sum_i h_i} \frac{\Delta V_i}{\Delta d_{p_i}} \tag{61}$$

If $M(d_p)$ and $F(V)$ are, respectively, the mass PSD and the experimental fractogram, the total mass of particles can be expressed by Equation (62):

$$\sum_i M^i(d_p)\Delta d_i = \sum_i F^i(V)\Delta V_i \tag{62}$$

and, by considering the relationship between the retention volume and the particle size, $V = g(d_p)$, and its derivative $g'(d_p)$ (Equation 63),

$$g'(d_p) = \frac{\Delta V_i}{\Delta d_i} \tag{63}$$

Equation (62) becomes Equation (64):

$$\sum_i \frac{M^i(d_p)}{g'_i(d_p)} \Delta V_i = \sum_i F^i(V)\Delta V_i \tag{64}$$

and, consequently (Equation 65),

$$F^i(V) = \frac{M^i(d_p)}{g'_i(d_p)} \tag{65}$$

For example, Equation (47) can be expressed as Equation (66):

$$\overline{d}_m = \frac{\sum_i d_i M^i(d_p)\Delta d_i}{\sum_i M^i(d_p)\Delta d_i} = \frac{\sum_i d_i F^i(V)\Delta V_i}{\sum_i F^i(V)\Delta V_i} \quad \text{etc.} \tag{66}$$

The acquisition of the experimental data and treatment of the fractogram are usually performed by a computer connected on line to the separation system.

3 METHODS, TECHNIQUES AND THEIR APPLICATIONS

The retention parameters R or λ are directly related to the effective diameters of the separated particles for some of the polarization techniques, such as sedimentation FFF. This relationship is not straightforward for some other polarization FFF methods. For example, λ is a complex function of the size and charge for electric FFF. It is a function of the thermal diffusion factor, which is a function of the diffusion coefficient and of the coefficient of the thermal diffusion, and the diffusion coefficient is inversely proportional to the size of the fractionated species, but a definite form of this dependence does not exist in thermal FFF.

The transverse positions of the zones and, as a result, the values of Γ_{max} in focusing FFF are related to the corresponding extensive properties of the fractionated samples, such as the density. The intensive properties often influence the width of the focused zones.

FFF is then used to characterize and to analyze quantitatively the properties related to the retention. Even if the determined characteristic of the separated sample is not explicitly related to the retention parameter, an empirical calibration can be established by first using known standards which are subsequently applied thereafter to determine this characteristic of the sample under investigation.

3.1 Polarization Field-flow Fractionation

The character of the applied field determines the particular method of polarization FFF. The most important of them, which have already found many practical applications in particle size analysis, are sedimentation FFF, flow FFF, electric FFF, and thermal FFF.

Other techniques have been proposed but their routine laboratory practice remains to be elaborated.

3.1.1 Sedimentation Field-flow Fractionation

This technique is based on the action of gravitational or centrifugal forces on the suspended particles. The sedimentation velocity is proportional to the product of the effective volume and density difference between the suspended particles and the carrier liquid. The channel is placed inside a centrifuge rotor, as shown in Figure 18. The technique can be applied to the analysis and characterization of polymer latex particles, inorganic particles, emulsions, biological cells, etc. The retention parameter λ depends on the effective mass of the particles according to Equation (67):

Figure 18 Schematic representation of sedimentation FFF channel.

$$\lambda = \frac{6kT}{\pi d^3 g w \Delta\rho} \tag{67}$$

where g is the gravitation or centrifugal acceleration and $\Delta\rho$ is the density difference between the particles and the carrier liquid. Calculation of the PSD is possible directly from the retention data by applying Equation (67) without any calibration.

The fractionation and analysis of colloidal particles in river water, the analysis of diesel exhaust soot, and of nuclear energy-related materials, are typical examples of the use of sedimentation FFF in the investigation of environmental samples.[26] Oil emulsions can also be analyzed by sedimentation FFF. Biopolymers and particles of biological origin are among the most interesting objects to have been fractionated.[15,27] The performance of sedimentation FFF is superior to or as good as other separation methods. A complication in interpreting experimental data is that the retention is proportional to the product of particle size and particle density. When performing fractionation in a single carrier liquid, the density must be assumed constant for all particles. However, it is possible to determine the size and density of the particles independently if fractionations are performed in more carrier liquids of various densities.

A typical application[28] of sedimentation FFF which allowed detection of a bimodal PSD in a sample of a polymer latex (supposed originally to have a very narrow and monomodal PSD) is shown in Figure 19(a). The order of the elution from the small to the large diameter particles corresponds to the polarization mechanism. Figure 19(b) shows a rapid, high resolution sedimentation FFF of the polymer latex particles.[29] The separation was carried out at high centrifugal force; the mechanism of steric FFF dominated, and the order of the elution was inverted.

Figure 19 (a) Fractogram of poly(glycidyl methacrylate) latex showing the bimodal character of the PSD not recognised by electron microscopy. (b) Fractogram of high-speed high-resolution sedimentation FFF of latex beads obtained by steric separation.

Figure 20 Dependence of the retention ratio on particle size for polarization and steric mode FFF at two different centrifugal forces. The dotted curve is for the lower force.

The domains of two competitive mechanisms are shown in Figure 20. The retention ratio decreases with increasing particle size in the range of the polarization mechanism and increases when the steric FFF mechanism prevails. When both mechanisms are in competition, the particles of different sizes can elute unseparated. However, if the field force is modified, the domain of the simultaneous action of both mechanisms can be displaced to avoid the deterioration of the separation.

Refinements to sedimentation FFF have generated new applications of this technique to the PSD analysis of samples of very diverse origin.[30–42]

3.1.2 Flow Field-flow Fractionation

Flow FFF is a universal method because the cross-flow, perpendicular to the flow of the carrier liquid along the channel, creates an external hydrodynamic field that acts on all particles uniformly,[43,44] and separation of particles of different sizes is caused by the differences in diffusion coefficients. The channel (Figure 21) is formed between two parallel semipermeable membranes fixed on porous supports, which maintain the uniform distribution of the cross-flow over the whole surface. The carrier liquid can permeate through the semipermeable membranes but the separated particles cannot. The retention parameter λ is given by Equation (68):

$$\lambda = \frac{kTV_0}{3\pi\mu V_C w^2 d_p} \tag{68}$$

where V_0 is the void volume of the channel, μ is the viscosity of the carrier liquid, and V_C is the volumetric velocity of the cross-flow. Flow FFF can also be carried out in a circular cross-section capillary. Radial forces are due to an internal over-pressure[45] which causes flow of the carrier liquid through the semipermeable cylindrical capillary. The advantage of this arrangement is lower dilution of the separated particles during elution, which is caused by a partial depletion of the liquid due to the radial cross-flow.

One example of an interesting application of flow FFF is shown in Figure 22: the retentions of two silica samples injected separately and in a mixture[46] indicated that the separation was not influenced by interactions between two particulate samples. The availability of the membranes and semipermeable capillaries compatible

Figure 21 Diagram of a flow FFF channel.

Figure 22 Flow FFF fractograms of two different samples of colloidal silica obtained separately (peaks 1 and 2) and in a mixture (peak 3).

with various solvents allows the operation of flow FFF with both water-based and organic solvents.

The original construction of the flow FFF channel was proposed and implemented experimentally.[47–53] Only the accumulation wall of the channel is semipermeable, so that a part of the carrier liquid passes through the membrane thus generating the hydrodynamic flow field across the channel. In order to optimize the linear velocity of the longitudinal flow, the channel width decreases from the inlet to the outlet.[53] However, the hollow fiber capillary used as a fractionation channel was found to be a simple and convenient solution for flow FFF.[54] Some selected review articles demonstrate a large field of practical applications of flow FFF in PSD analysis.[55–57]

3.1.3 Electric Field-flow Fractionation

Electric FFF uses an electric potential drop across the channel to generate a transverse flux of charged particles.[58] The walls of the channel are usually formed by semipermeable membranes that allow the passage of the small ions but not the permeation of the separated particles (Figure 23). The dependence of the retention parameter λ on the electrophoretic mobility μ_e, and the diffusion coefficient of the charged particles is given by Equation (69):

$$\lambda = \frac{D}{\mu_e E w} \tag{69}$$

Figure 23 Diagram of an electric FFF channel.

where E is the electric field strength. The ratio of the diffusion coefficient to the electrophoretic mobility of the particles determines the retention in electric FFF. The particles exhibiting only small differences in electrophoretic mobilities but with an appreciably broad PSD and, consequently, important differences in diffusion coefficients, can be separated. The advantage of electric FFF compared with electrophoretic separations such as capillary electrophoresis, is that high electric field strength can be achieved at low absolute values of the electric potential due to a small distance between the walls of the channel.

Electric FFF is especially suited to separations of biological cells as well as charged polymer latexes and other colloidal particles. The separation is strongly influenced by the concentration of the injected sample, the concentration of the buffer solution, the pH, and by interparticle interactions. This can produce experimental difficulties for conventional fractionations; however, it can be exploited for investigation into the interactions of charged particles. As for flow FFF, electric FFF can be carried out by using a semipermeable tube of circular cross-section with the electric field applied transversally.[43,59] Fractionation of charged particles represents a wide field of application.[60–65]

3.1.4 Thermal Field-flow Fractionation

Thermal FFF was the first experimentally implemented technique.[16] Until recently it was used mostly for the fractionation of macromolecules; now there have been some attempts to apply this method to the fractionation of particles. The future potential of thermal FFF justifies a brief description of this technique, regardless of its recent limited use for the PSD analysis.

The temperature difference between two metallic bars, forming the channel walls with highly polished surfaces and separated by a spacer in which the channel proper is cut, produces the flux of the sample components, known as Soret effect, usually toward the cold wall. The construction of a channel for thermal FFF is shown in Figure 24.

Figure 24 Diagram of a thermal FFF channel.

The relation between the λ, characteristics of the fractionated particles, and the operational variables is given by Equation (70):

$$\lambda = \frac{D}{wD_T(dT/dx)} \tag{70}$$

where D_T is the coefficient of the thermal diffusion which depends on the chemical composition and structure of the fractionated species but not on their size. As a result, the differences in thermal diffusion coefficients allow fractionation according to differences in chemical composition and structure. However, the diffusion coefficient D depends on the size which should allow fractionation according to PSD.

Although it might appear possible to evaluate molar masses or particle sizes from an experimental fractogram by using simply Equation (70), an empirical calibration curve (Figure 25[66]) is usually constructed by using a series of samples of known characteristics. The experimental retention ratios are used to plot the calibration curve. This calibration can be used to determine the characteristics of an unknown sample of the same chemical composition and structure with the same temperature gradient applied.

The most frequent applications of thermal FFF concern polymers. The pressurized separation systems permit operation above the normal boiling point of the solvent used. The fractionations can be finished in few minutes or seconds. Performance parameters favor thermal FFF over the competitive methods, at least for the fractionation of macromolecules. The fractogram in Figure 26(a) shows a wide range of the polymer molar masses which can be determined in a single experiment by using time-programmed temperature gradient.[67] Figure 26(b) demonstrates ultrarapid and high-resolution thermal FFF.[68]

As concerns the fractionation of the particles and consecutive analysis of the PSD, the actual potentials of thermal FFF have to be verified experimentally and theoretically. It has been shown that various particles

Figure 25 Calibration curve $R = f(M)$ for a thermal FFF channel for polystyrene standards at a given temperature gradient.

Figure 26 Fractograms of different molar mass polystyrenes: (a) obtained with temperature gradient programming and of polystyrene standards of different molar masses; (b) showing an ultrarapid separation.

exhibit retention in thermal FFF.[69,70] However, the retention phenomenon is driven by surface properties of the retained particles[71–75] and, consequently, the characterization of PSD of a studied sample from thermal FFF data is not yet easy.

3.1.5 Other Polarization Field-flow Fractionation Methods

Other polarization FFF methods include magnetic FFF, concentration FFF (making use of a concentration gradient of a mixed solvent to induce the chemical potential gradient), and shear FFF. Although these methods may become highly relevant for PSD analysis in the near future, their recent technical level does not allow their routine use.

Each of the above-described polarization FFF methods can apply the field, of constant or variable strength, during the fractionation. Steric FFF is applicable independently of the physical character of the field, but gravitation or centrifugal forces or the cross-flow of the carrier liquid are the most frequently used for the fractionation of practically important particles such as the coal particles,

human and animal cells, particles originating from the environment, etc. Precautions must be taken to prevent problematic situations that can occur when some particles may undergo steric exclusion, with the elution order from large to small, while other particles can experience polarization, with the elution order inverted.

3.2 Focusing Field-flow Fractionation

Focusing FFF is less developed than polarization FFF and, consequently, has not yet been exploited in routine laboratory work due to its substantially shorter history. Focusing FFF methods can be classified according to various combinations of the driving field forces and gradients:

- effective property gradient (perichoric gradient) of the carrier liquid;
- preformed perichoric gradient;
- cross-flow velocity gradient;
- lift forces;
- shear stress;
- gradient of nonhomogeneous field action.

These principles are promising for PSD analysis and merit brief discussion here.

3.2.1 Perichoric Gradient of the Carrier Liquid Combined with a Field

Focusing can occur due to the effective property gradient of the carrier liquid in the direction across the channel, combined with a primary or secondary transverse field. The density gradient as in SFFFFF or the pH gradient as in isoelectric focusing field-flow fractionation (IEFFFF) have already been implemented.[9,10,12,13,76,77] Two simple channels are demonstrated in Figures 27(a) and 28(a) as well as two examples of practical applications showing the separation of two types of the polystyrene latex particles by SFFFFF (Figure 27b) and the separation of two components of horse myoglobin by IEFFFF (Figure 28b). The separation by SFFFFF was carried out according to the density difference of the latex particles, whereas the electric field was applied to generate the density gradient in a suspension of charged silica particles. The separation by IEFFFF was carried out according to the isoelectric point differences by using the electric field to generate the pH gradient and to focus the sample components.

Retention theory for the special case of focusing FFF in a density gradient is developed here in more detail because a similar approach can be applied to all the methods and techniques described below. The transverse gradient can be generated, for example, in a binary or multicomponent carrier liquid whose two or more components are affected unevenly by the primary

Figure 27 (a) Diagram of a channel for focusing FFF in coupled electric and gravitational fields: (1) input, (2) output, (3) electrodes and (4) spacer. (b) Fractogram of two samples of polystyrene latex particles showing a good resolution obtained by focusing FFF, whereas no detectable resolution was achieved under static conditions: (1) injection, (2) stop-flow period, peaks corresponding to particle diameters of (3) 9.87 μm and (4) 40.1 μm.

homogeneous field. The primary field can also act to form the focused zones of the separated sample components. Another possibility is to superimpose a secondary field of different nature on the gradient generated by the primary field.[9,10,12,13] The density gradient can be generated by centrifugal or electric field forces acting on colloidal particles, suspended in a liquid. The concentration distribution of the perichoric modifier particles due to the primary field is described by identical exponential distribution function as in the case of polarization mechanism (Equation 71):

$$c_{\mathrm{m}}(x) = c_{\mathrm{m}}(0) \exp\left(\frac{-x|U|}{D_{\mathrm{m}}}\right. \qquad (71)$$

Figure 28 (a) Diagram of a channel for IEFFFF. (b) Fractograms: (1) without the electric field applied; and with the active field showing the separation of (2) acidic and (3) basic components of horse myoglobin.

The subscript m specifies the parameters concerning the modifier. The concentration $c_m(0)$ in Equation (71) can be calculated from the relationship for the average concentration $c_{m,ave}$ which is equal to the known initial concentration (Equation 72):

$$c_{m,ave} = \frac{\int_0^w c_m(x)\,dx}{\int_0^w dx} = c_m(0)\frac{D_m}{wU_m}\left(1 - \exp\left(\frac{-wU_m}{D_m}\right.\right. \tag{72}$$

Substituting into Equation (71) gives Equation (73):

$$c_m(x) = \frac{c_{m,ave} wU_m}{D_m(1 - \exp(-wU_m/D_m))}\exp\left(\frac{-xU_m}{D_m}\right. \tag{73}$$

The focusing force proper can be generated by combining the transverse gradient and the primary or secondary field action. Primary electric field can be applied to generate the density gradient due to the migration of the charged colloidal particles. The secondary gravitation coupled simultaneously with the established density gradient causes the focusing of a particulate sample component.

A modified version of Equation (20) for the focusing force gradient can be used to describe the focusing effect under these specific conditions (Equation 74):

$$\frac{dc_i}{c_i} = -\frac{U_i(x)}{D}\,dx \tag{74}$$

where c_i is the concentration of the focused sample component. The subscript i is used to distinguish between the concentration distribution, $c_i(x)$, and the related parameters of the ith focused sample component and the concentration distribution, $c_m(x)$, and the related parameters of the gradient forming component of the carrier liquid. Equation (73) can be transformed into density terms instead of concentrations (Equation 75):

$$\rho(x) = \rho_l + \frac{\phi_{m,ave}\Delta\rho_m wU_{m,e}}{D_m(1 - \exp(-wU_{m,e}/D_m))}\exp\left(\frac{-xU_{m,e}}{D_m}\right. \tag{75}$$

The macroscopic focusing force acting on a single focused species can be calculated from Equation (76):

$$F_i(x) = (\rho(x) - \rho_i)v_i g_f \tag{76}$$

The concentration distribution of the focused particles in a density gradient formed simultaneously due to the action of primary electric field on two component colloidal carrier liquid is obtained by substituting into Equation (74) and by integration (Equation 77):

$$c_i(x) = c_i(x_{max})\exp\left\{-\left(\frac{v_i g_f \phi_{m,ave}\Delta\rho_m w}{kT(1 - \exp(-wU_{m,e}/D_m))}\right.\right.$$
$$\times\left(\exp\left(-\frac{xU_{m,e}}{D_m}\right.\right. - \exp\left(-\frac{x_{max}U_{m,e}}{D_m}\right.\right.$$
$$\times\left.\left.\left(1 + \frac{U_{m,e}(x_{max} - x)}{D_m}\right.\right.\right\} \tag{77}$$

where v_i is the volume of the focused particle, g_f is the acceleration of the focusing field, $\phi_{m,ave}$ is the average volume fraction of the modifier, $\Delta\rho_m = \rho_m - \rho_l$ is the density difference between the modifier component and the suspending liquid and $U_{m,e}$ is the velocity of the modifier species due to the primary electric field. Equation (77) was obtained without assuming the constancy of the density gradient. The Gaussian distribution, Equation (22), deviates substantially from Equation (77).[9,10,12,13]

3.2.2 *Preformed Gradient Combined with a Field*

The effective property gradient of the carrier liquid, such as the density gradient, can be preformed at the beginning of the channel and combined with the primary or secondary field forces. The step density gradient is formed in such a case. The preforming is not limited to density gradient. A scheme of an experimental arrangement for this method and a typical experimental result[78,79] is shown in Figure 29.

3.2.3 *Cross-flow Velocity Gradient Combined with a Field*

The focusing occurs in the transverse flow velocity gradient of the carrier liquid which opposes the action of the field. The longitudinal flow of the liquid is imposed simultaneously. This elutriation focusing field-flow fractionation (EFFFF) method has been investigated experimentally by using the trapezoidal cross-section channel[80,81] but use of the rectangular cross-section channel is possible. The principle of the method and the result of fractionation of micrometer-size polystyrene latex particles are demonstrated in Figure 30.

3.2.4 *Lift Forces Combined with a Field*

The hydrodynamic lift forces that occur at high flow rates of the carrier liquid combined with the primary field, are able to concentrate the suspended particles into the focused layers.[82] The retention of the particles under the simultaneous effect of the primary field and lift forces generated by the high longitudinal flow rate can vary with the nature of various applied primary field forces.

3.2.5 *Shear Stress Combined with a Field*

A high shear gradient in a carrier liquid can lead to the deformation of soft particles. The established entropy gradient generates the driving forces that displace the particles into a low shear zone.[83] At a position where all the driving forces are balanced, the focusing of the sample components can occur.[84] Although this method was originally proposed for a temperature gradient acting as a primary field, generating the thermal diffusion flux of the macromolecules which opposes the flux due to the entropy changes generated motion, in principle it should be applicable to soft particles as well.

3.2.6 *Gradient of a Nonhomogeneous Field*

A nonhomogeneous high-gradient magnetic field can be used to separate various paramagnetic and diamagnetic particles of biological origin by a mechanism of focusing FFF.[85] A concentration of paramagnetic particles near the center of the cylindrical capillary and the focusing

Figure 29 (a) Diagram of a separation channel for isopycnic focusing FFF in preformed stepwise density gradient. (b) Evolution of two focused layers of the particles at three different longitudinal positions inside the channel: (1) a layer of the particle mixture positioned at the interface between two different density liquids at the beginning of the separation; (2) evolution of the separation of different density particles; (3) two zones focused at the interfaces of different density liquids.

Figure 30 (a) Principle of EFFFF in a trapezoidal cross-section channel. Focused zones are formed due to the field forces and the opposite velocity gradient of the carrier liquid flow across the semipermeable lower and upper walls of the channel. Separation of the focused zones in the direction of the longitudinal flow in trapezoidal cross-section channel is facilitated by the formation of axially asymmetrical flow velocity profile. (b) Fractogram showing the separation of two polystyrene latexes of (1) 1.6 μm diameter and of (2) 5 μm in diameter particles.

of diamagnetic particles in a free volume of the capillary should occur. To our knowledge, no experimental results have yet been published.

3.2.7 Other Possibilities

Other gradients and a variety of fields can probably be combined to produce focusing, making these phenomena suitable for PSD analysis. The above discussions on the mechanisms exploited in focusing FFF give an idea as to their potential. More information on the state of the art can be found in a review.[86]

4 CONCLUDING REMARKS

Scientific progress passes through discoveries, inventions, and innovations. As a specific scientific discipline, analytical chemistry follows this process but also in the context of the whole area of scientific research. The polarization and focusing FFF methodologies represent an important contribution to the science and technology of separation, and the analysis of particles of synthetic or natural origin over a wide range of sizes, and of organized structures such as cells and microorganisms. Research and technology related to the life sciences and to macromolecular chemistry and technology, the analytical problems appearing in context with the protection of the environment, and many other scientific and technological activities, have stimulated the development of new analytical separation methods. The article shows that important contributions to experimental implementations have been obtained with model systems. The availability of commercial instrumentation systems is a crucial factor with regard to the progressive introduction of FFF methodologies into current laboratory practice. Moreover, it is important to recognise that all components of the apparatus are absolutely identical to those for liquid chromatography, with one exception – the separation channel. A liquid chromatograph can be modular, being composed of individual commercially available parts, such as the pump, injector, detector, etc., with a column that can be changed for individual applications. The FFF apparatus can be assembled similarly, with various channels which, in most cases, are easy to construct.

Filtration is defined as the separation of solid particles from a liquid or gas by passing the suspension through a porous, fibrous or granular substance. In science and industry, filtration is commonly used for the concentrating and/or removal of particulate matter or for the separation of particles into size classes for subsequent physical, chemical or biological analysis. Separation of particles into multiple size classes is often required for the assessment of particle size. There are many different types of filters available (e.g. fibrous, membrane, polycarbonate) for particle characterization through filtration. The type of filter to be used for particle size characterization is dependent on a number of considerations such as sample (particle) characteristics, collection efficiency, pore size and structure and analytical compatibility. Filtration has the advantage of being one of the few techniques which allow for the physical separation of particles into different size classes for distribution or chemical–biological analysis. If appropriate precautions are taken to minimize sample perturbations (e.g. select appropriate filter for the application, filter in the field, avoid overloading a filter, ensure a low flow rate and stir if possible), a reasonably accurate estimate of particle size can be obtained. Generally, errors associated with filtration arise from filter clogging and when attempting to characterize flocculated/aggregated particles. The basic nature of a suspended aggregate (i.e. fragile, plastic, high water content) means that it is likely to be broken up or created owing to the often tortuous nature of filtration, or be deformed on the surface or within the filter owing to pressure effects. This has implications if optical image analysis of the filter is to be used for particle size analysis as the true particle morphology and size will have been altered. In such an instance, if only a grain size distribution is required, it is suggested that optical image analysis be employed in conjunction with a plankton chamber settling technique rather than with filtration.

1 INTRODUCTION

Particles, and their interactions with their surrounding environments, have both theoretical and practical relevance within science and industry. Physical, chemical and biological processes are at play with or within particles and as such are known to play an important role in the biological and chemical dynamics of any aquatic and terrestrial environment and within engineered systems such as wastewater treatment. The definition of a ''particle'' in science is wide and varied depending on the discipline, and may incorporate a wide range of sizes, compositions and structures. Particles are considered to be dynamic and, in most cases, unstable relative to their surrounding environment, resulting in the majority of cohesive particles ($<63\,\mu m$) existing primarily as flocculated or aggregated particles[1,2] with a high propensity to assimilate and transport various nutrients and contaminants.[3] As such, an accurate determination of particulate characteristics is of vital importance when dealing with issues of sediment and contaminant interactions. Common physical measurements of particle characteristics important to industry and the environment include grain size, surface area, specific gravity, surface charge, bulk density, sheer stress, porosity and permeability.[4] Grain size is the most significant of these characteristics in terms of a particle's capacity to concentrate and retain contaminants owing to its controlling influence over many of the above characteristics.[4–11] Hence, if only one physical characteristic of a particulate matter is to be determined for

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

industrial or environmental purposes as related to contaminants, grain size is by far the characteristic of choice.

Investigations into the chemically active fraction (<63 μm[12]), the effects of particle size on the adsorption of contaminants[11,13,14] and the association of microbes with particles,[15] among others, often require that (a) the sediment be separated into a number of size fractions for subsequent analysis and/or (b) an accurate grain size distribution be obtained of the original sample. Such information and the associated chemical and/or biological analyses are often driven by environmental concerns, process control and monitoring demands and the development of new materials requiring evaluation. Accurate monitoring of particulate matter requires a knowledge of particle size distributions to assess fully health hazards, environmental conditions and industrial process efficiencies/deficiencies or performance. Particle fractionation and distributions are often used within models for sediment and contaminant source, fate and effect predictions in support of, or development of, environmental policies and management of water resources including wastewater treatment.

While there are a number of reviews of direct and indirect techniques for the fractionation of particulate matter into grain size ranges or for the determination of a particle size distribution,[4,16–20] there is no standard technique, and as such, each method can produce significantly different results (this is particularly true when dealing with particles in aggregate form, as the majority of methods do not maintain the integrity of the particles). Grain size analysis is therefore an operationally defined property.

Direct optical image analysis with plankton chambers or filters provides the least destructive (to aggregates), most accurate, direct method of determining grain size distributions. However, if particle separation is required there are four other categories of techniques which allow for the separation of particles into size classes with a minimum of particle perturbation:[20]

1. sieving, filtration, ultrafiltration and dialysis
2. sedimentation and centrifugation
3. field flow fractionation
4. hydrodynamic chromatography.

To date, categories 1 and 2 have been the most widely used methods for particle fractionation. Within these two categories, filtration, in spite of its drawbacks, is probably the most widely used, as its operational size range spans from the colloidal fraction up to and past what is considered the chemically active fraction (Figure 1). In addition, the chemical conditions in solution can be well controlled and particle size separation is generally well defined given appropriate controls. The primary chemical drawbacks are (a) possible contamination by metals and organic matter from the filter materials, (b) adsorption of ''dissolved'' compounds at the filter surface and (c) reactions induced by the filter, such as

Figure 1 Size ranges for separation techniques and for the general filter types. (Modified with permission from J. Buffle, D. Perret, M. Newman, 'The Use of Filtration and Ultrafiltration for Size Fractionation of Aquatic Particles, Colloids and Macromolecules', in *Environmental Particles*, eds. J. Buffle, H. van Leeuwen, Lewis Publishers, Chelsea, MI, 1992. Copyright, CRC Press, Boca Raton, FL.)

aggregation of adsorbed natural organic material and adsorption of inorganic ions by particles retained on or within the filter.[21] An understanding of the chemical interaction between particles, solute and filters is an important analytical requirement for any chemical or biological focused study. This relationship is beyond the scope of this article and only the physical aspects will be addressed. The primary physical drawbacks are related to the particle (aggregate) morphological changes and filter clogging resulting in a poorly defined size threshold. While sieving can be used for the fractionation of larger particles (most often used in the soil sciences) and ultrafiltration can be used for the fractionation of colloidal particles (although with great cost and time consumption), this article will focus primarily on the use of pressure or vacuum filtration in particle sizing and the appropriate size ranges associated with this method (Figure 1). In addition, the use of filters or plankton chambers with image analysis will also be discussed as a viable way of obtaining a grain size distribution. Although filtration is widely used for the filtration of aerosols from gases,[22,23] this article will focus specifically on the sizing of particles from natural or engineered aqueous suspensions.

2 DEFINITIONS

2.1 Particle

It is universally accepted, and fundamental to science, that all matter is composed of particles. Figure 2 provides a breakdown of what in environmental science generally is considered a particle. As with most definitions within science, however, the definition of a ''particle'' is operationally defined. Its definition in terms of composition, size range and structure is dependent on the objectives of the investigation, the process and environment under study and the operational restriction around the available tools or techniques for analysis. While there is no standard definition of a particle, the general standard size cutoff as to what would be considered a particle versus the dissolved phase is arbitrarily set at 0.45 μm.[11,21]

The difficulty in providing a standard definition of a particle is further complicated by the knowledge that particles rarely exist in a homogeneous state, with the exception of larger particles such as quartz (even this is debatable depending on the scale of observation, as such particles are likely to have bacterial, organic or ionic associations or coating of some sort) or smaller organisms such as bacteria (these too can often be incorporated within aggregated particles). These aggregates and flocs generally consist of an interrelated network of organic and inorganic particles resulting in complex physical, chemical and biological interactions not only within themselves but also with the medium in which they exist as a whole. These complex interactions, which will affect aggregate or floc function and structure, are illustrated in the conceptual model of floc form and function provided in Figure 3. A common problem within analytical chemistry is that all too often particle evaluations are performed on the constituent or absolute particles of the aggregates and not on the aggregates themselves. Such disregard for the integrity of the true particle structure and distribution can lead to erroneous results in evaluation or implementation of such important issues as environmental management/policy, health risk assessment and industrial performance.

Given that environmental analytical chemistry will focus mostly on the chemically active fraction (<63 μm), and that this fraction exists extensively as composite particles,[1,2] this article will focus only on the sizing and fractionation of individual particles and flocculated or aggregated particles and their constituent particles down to a size of 0.45 μm. Therefore, for the purposes of this article, the term ''particle'' will be limited by structure and size and be defined as follows:

> any physical entity or combination (aggregate/floc) of entities (inorganic or organic, viable or non-viable) within the solid phase having a minimum diameter within the range of 0.45 μm to the aggregate/floc size that a given environment will support (to a maximum 1000 μm).

This article will focus mostly on particles immersed or suspended within natural waters or within hydrous-engineered media and will not include soil-type aggregates or aerosols. The colloidal fraction will not be addressed here because of the extremely different physicochemical characteristics of these particles.[24,25] A complete discussion on colloidal characterization can be found in Leppard and Buffle.[26] The size range stated above is that which can be easily viewed by standard optical microscopy. For the purposes of this article, a floc is defined as a particle which has resulted from aggregation within an aquatic medium (suspended or bed sediment) and an aggregate is a particle which has resulted from aggregation outside an aquatic environment (e.g. soil particle). Aggregates can be observed and transported within the aquatic environment owing to their delivery to the system by land-surface processes (e.g. stormwater runoff). Flocculation and aggregation will be used interchangeably within this article.

2.2 Particle Size

While the definition of a particle above is based in part on size, a brief discussion of what defines the size of a particle is required based on the methods to be evaluated in this article.

Figure 2 Schematic classification of what environmental science generally considers as dissolved, colloidal and particulate compounds as defined by size and organic and inorganic components. All of the components to the left of the flocculation wedge can be incorporated into flocculated or aggregated particles with a subsequent increase in effective size. No upper size range for floc size can be determined as it is dependent on a number of physical, chemical and biological factors, although marine snow has been observed in the order of centimeters. (Modified with permission from J. Buffle, D. Perret, M. Newman, 'The Use of Filtration and Ultrafiltration for Size Fractionation of Aquatic Particles, Colloids and Macromolecules', in *Environmental Particles*, eds. J. Buffle, H. van Leeuwen, Lewis Publishers, Chelsea, MI, 1992. Copyright, CRC Press, Boca Raton, FL.)

Convention dictates that most methods of particle sizing provide results in terms of particle diameter (or a range of possible diameters). In nature and in most industrial processes, particles are, however, not geometrically perfect spheres, squares, or the like, but rather constitute irregularly shaped particles. This is particularly true for flocs where the particles are not only irregular in shape but also in composition and density. Such complexity requires that an equivalent diameter be measured or derived from a given technique. Allen[27] provides 13 different measures of particle diameter which are based on one or all of the following physical characteristics of (1) the particle (e.g. volume, surface area), (2) the suspension (density and viscosity of the fluid relative to the particle during settling) and (3) the filter (pore size). As this article focuses only on filtration and optical size determination, particle size will be defined as follows:

Filter Particle Diameter: the width of the minimum aperture through which a particle will pass. In reality, however, filtration only provides a particle size range and not an estimate of discrete particle size (unless assessed optically under a microscope). A given filter will, therefore in theory, retain all particles on or within a filter whose particles are larger than the nominal or average pore size of the filter.

Figure 3 Conceptual model of floc form and function. (Reproduced with kind permission of Kluwer Academic Publishers from I.G. Droppo, G.G. Leppard, D.T. Flannigan, S.N. Liss, 'The Freshwater Floc: a Functional Relationship of Water and Organic and Inorganic Floc Constituents Affecting Suspended Sediment Properties', *Water Air Soil Pollut.*, **99**, 43–53 (1997).)

Optically Derived Equivalent Spherical Diameter: optical size determination of sediment sizes retained on a filter or in a plankton chamber is represented as a distribution of equivalent diameters. That is, the diameter of a sphere whose cross-sectional area is equal to the projected area of the particle.

2.3 Filtration

Filtration can be defined as the separation of solid particles from a liquid or gas by passing the mixture through a porous, fibrous or granular substance. In science and most industrial processes, filtration is most commonly used for the concentrating of particulate matter or for the separation of particles into size classes through sequential or cascade filtration for subsequent physical, chemical or biological analysis. Separation of particles into multiple size classes is also commonly used for the determination of grain size distributions (derived through a mass-balance approach). There are several mechanisms by which particles are removed from a given medium during filtration.[23,28–30] These are as follows:

Interception: occurs when a particle moving within a flow streamline comes in contact with the surface of the filter. Interception is most important when the ratio of particle diameter to the pore size is relatively large. The importance of this mechanism increases as filter clogging or caking occurs. Modeling efforts[31] have shown that for particles larger than 1 μm, interception is the main mechanism of particle removal suggesting that retention is a function of filter geometry and particle size and is independent of particle density, diffusivity, particle settling velocity and fluid velocity.

Inertial Collection: occurs when the flow streamline bends around a filter fiber or within a pore, but the inertia of the particle keeps it on its original track so that it impacts the filter surface. This mechanism is most important when the flow velocities are high and when fiber filters are employed.

Brownian Diffusion: occurs primarily with colloidal particles (<0.5 μm). There is an inverse relationship between the importance of this mechanism and particle size. Particles follow the flow stream to the surface of the filter where the concentration is initially zero. This mechanism works best with low flow rates as the time spent by a colloidal particle in the vicinity of the filter surface increases, resulting in enhanced diffusional removal.

Electrostatic Deposition: occurs through electrochemical attractions between the filter and the particle. This can be important for colloidal particles; however, it is generally neglected unless the particles or filters have been charged in some quantifiable way.

Gravitational Settling: generally gravitational settling is insignificant during filtration in aqueous media as the ratio of particle terminal settling velocity to the free stream velocity is small. This mechanism will only be important for very large particles which are above the range discussed in this article.

These mechanisms (excluding electrostatic deposition and gravitational settling) have been reviewed as related to modeling of filtration processes by Logan[30] and Logan et al.[31] Filtration models can be used to determine whether samples should be filtered in series or in parallel and to determine the appropriate filter types and pore sizes for different applications related to particle sampling and sizing. The actual mathematical modeling of filtration is beyond the scope of this article.

3 EQUIPMENT

3.1 Filter Types

There are numerous reviews of filter types, structures, compositions and applications.[29,31–35] Filters consist of either tightly woven fibrous mats of natural or synthetic materials or plastic porous membranes. Consideration as to what type of filter to use for a specific application in particle characterization requires a knowledge of a number of factors including cost, availability, collection efficiency, compatibility with the analytical and sampling procedures, compatibility of the filter pore size with the sample particle size range, the ability to remove particles for analysis following filtration, chemical inertness and sterilization considerations. Many filters (particularly membrane), depending on their composition and the digestion procedure used, can be digested along with the sediment for chemical analysis. If the filtrate is to be analyzed for the ''dissolved'' phase, care must be taken to choose the best filter type as this can have a profound effect on the filtrate chemical characteristics.[36] Filters come in a number of different sizes and formats. Cartridge filters, commonly used in industry, will not be discussed here as they are not appropriate for the sizing of particles. Commonly used filter media are listed below, with the general physical characteristics of each filter type given in Table 1 and environmental scanning electron micrographs of the surfaces of these filter types in Figure 4(a–d). For the purposes of this article, all separation media described will be referred to as filters although many can and are also called screens, nets or sieves.

Screens, nets or sieves are generally used for larger size particle separation and are basically a weave of usually nylon fibers with pore shape dictated by the nature of the weave (e.g. Nitex™). A number of different weaves are available, the square weave (square pores) being one of the most common.[37]

Fibrous filters (depth filters) are tightly woven mats of materials such as glass, cellulose (paper), quartz, silk, polyester, rayon or plastic fibers. These filters are relatively inexpensive, widely available (e.g. Whatman™ paper filters) and have high flow rates and high collection efficiencies for a wide range of particle sizes, with the cellulose filters appropriate for high-temperature ashing. They are not appropriate if the retained sediment is required to be removed from the filter prior to analysis, particularly if the sample is dominated by cohesive sediments. This is primarily due to the entrapment of sediments within the filter mat and the large surface roughness relative to the diameter of the particles. These filters are primarily used for clarification and removal of large particles. Often depth filters are used as prefilters in order to reduce clogging of membrane filters. Chemical inertness is questionable with regard to glass and quartz fiber filters as metal ions are strongly adsorbed, while the affinity of organics to quartz fibers can result in an overestimation of organic carbon concentration and mass.[21,23,35]

Table 1 General physical characteristics of filter types

Filter type	Fiber diameter (μm)	Pore diameter (μm)	Porosity (%)	Filter thickness
Fibrous	0.1–100	<1–100	60–>90	0.15–0.5 mm
Screen	28–1000	10–5500	2–72	1.9–0.045 mm
Membrane	N/A	0.01–10	<85	0.05–0.2 mm
Polycarbonate	N/A	0.1–8	5–10	6–10 μm

Figure 4 Micrographs of general filter-type surfaces: (a) woven mesh; (b) Nuclepore™ filters (polycarbonate); (c) membrane filters (cellulose nitrate or acetate); and (d) fiber filters (e.g. glass, paper fibers).

Membrane filters are porous membranes, such as Millipore™, composed of cellulose nitrate and cellulose triacetate (less common compositions are PVC, nylon, Teflon™ and silver). Teflon™ should be used for chemical studies as it is the most chemically inert although it cannot be used for analyzing organic species. Filtration on membrane filters results in the particles concentrating at or close to the surface of the filter. Unlike the fibrous filters, a membrane filter's loading capacity is limited. High pressure gradients are possible with resultant particle deformation.[21,23,35]

Polycarbonate pore filters (Nuclepore™) are smooth, sheet-like filters with cylindrical pores perpendicular to the surface of the filter.[21,23,35] Particles are collected at the surface of these filters, making them appropriate for particle wash-off for subsequent analysis (provided enough sample volume can be obtained) or microscopic observations and sizing of particles in the least disturbed state (albeit some particle flattening may occur of non-rigid particles such as flocs). These filters have a much smaller total void volume (porosity) and hence a lower flow rate than the other types of filters. Like other membrane filters, Nuclepore™ filters have a small load capacity before clogging occurs and high pressure gradients can result in particle deformation.[21,23,35]

3.2 Filtration Apparatus

While filtration apparatus is available in a number of different formats, generally at a minimal cost relative to other particle separation and sizing methods, to support a number of different filter types and sizes, they all generally consist of standard components. The most commonly used apparatus is a Millipore™-type filtration funnel that supports a 47-mm or 25-mm diameter filter. While larger apparatus are available to support filter sizes up to 30 cm in diameter, these types of apparatus are generally used for particle removal and solute analysis rather than for particle size analysis.[38] The type of apparatus used is

dependent on the requirements of the study and may be dictated by such factors as volume to be filtered, chemical requirements [stainless steel or plastic (generally polyethylene)], biological requirements (autoclavable or sealed units) and pressure restrictions. Often samples will be pretreated by processing the sample through a sieve (often 100 mesh, 0.15 mm) to define the particle size upper limit for filtration. A filtration system generally consists of the following components as illustrated in Figure 5 (only vacuum filtration is illustrated):

1. *funnel*: reservoir above the filter to hold the sample to be filtered, to allow for measurement of volume filtered and to provide a positive seal around the perimeter of the filter (can be plastic, Teflon™, glass or stainless steel);
2. *filter holder*: to hold the filter securely and to provide a positive seal around the perimeter of the filter (can be plastic, Teflon™, stainless steel or fritted glass);
3. *filtrate collection flask*: composition irrelevant for particle sizing; however, if the solute is to be chemically analyzed then consideration needs to be given to the makeup of the flask;
4. *source of vacuum/pressure*: electric, hand pump or water flow suction;
5. *supporting materials*: sieve for upper size class definition (composition important if chemical characterization is planned), spring clamp, stoppers, filtration hosing, filter tweezers (generally Teflon™ tipped), squirt bottle and overflow protection flask (optional).

Figure 5 Generic filtration apparatus components. Note that component size, shape, material and configuration will vary.

3.3 Sequential (Cascade) Filtration Apparatus

As the term implies, sequential filtration is simply the method whereby the sample is passed through a series of filters in descending order of nominal pore size. This process may be performed in a discontinuous fashion (i.e. one filter at a time) or in a continuous fashion with the filters stacked. Such methodologies have been described by Laxen and Harrison,[39] Tessier et al.,[40] de Mora and Harrison,[41] Rao and Kwan,[42] Buffle et al.[20] and Droppo et al.[43] and are depicted in Figure 6 (pore sizes indicated from Droppo et al.)[43] and would be considered to be filtration in series. This method may be modified by performing particle separation in parallel, that is, splitting a sample into the number of filters used, running a sample through its respective filter, and then determining grain size distributions by subtracting cumulative masses from consecutive filter retained masses (in descending order).

Figure 6 Generalized sequential filtration set-up. (Reproduced by permission of John Wiley & Sons Inc. from S.S. Rao, K.K. Kwan, 'Method for Measuring Toxicity of Suspended Particles in Waters', *Toxicity Assess.*, **5**, 91–101 (1990). Copyright © 1990, John Wiley & Sons Inc.)

3.4 Plankton Chamber

If the investigation is concerned only with obtaining a particle size distribution which is representative of the ''true'' size of the particles within a natural or engineered system, then the use of plankton chambers in conjunction with image analysis is recommended over filtration.

The plankton chamber (Hydro-Bios Kiel™) consists of four components (Figure 7): (a) a 3 mL reservoir with removable circular microscope slides in which the specimen comes to rest after settling, (b) a column available in various volumes (10, 25, 50 and 100 mL), (c) a top cap used to hydrostatically seal the plankton chamber and (d) a square piece of glass used to cover the reservoir after the column has been removed. In this technique the particulate sample may be introduced to the column section of the plankton chamber, either by a wide-mouth pipette (>3 mm) or the suspension can be sampled directly within the plankton chamber set up as described by Droppo and Ongley.[45] In general, within the field the appropriate column (Figure 7) volume is placed under the water and parallel to the direction of flow. The column is then capped under water and inverted upright for floc settling and subsequent observations such as that illustrated in the upper part of Figure 7. The size (volume) of the column used is dependent on the ambient suspended solids concentration (Droppo and Ongley,[45] provide a curve relating recommended column volumes to ambient concentration). Once sampled, the particles/aggregates/flocs settle under gravity until they come to rest on the microscope slide portion of the plankton chamber. Once at rest, the sample can be sized using an inverted microscope interfaced with any image analysis system capable of measuring particle size distributions. (There are many commercially available computer image analysis systems on the market spanning a wide range of price. These systems will not be discussed here.) Problems associated with the use of plankton chambers is that they are relatively expensive compared with standard filtration methods and the technique is concentration limited (also true for the optical analysis of particles on filters).[1,45]

Figure 7 Plankton chamber components: (a) 3-mL reservoir; (b) column; (c) top cap; and (d) square glass plate. (Reproduced by permission of the American Society of Microbiology from Droppo et al.[44])

4 PARTICLE SIZING BY FILTRATION

For the effective separation of particles into size classes by filtration, three criteria must be met:[41]

1. the stated filter nominal porosity must approximate the effective or experimentally observed porosity;
2. the filter pores should have a relatively uniform size;
3. the effective pore size should remain relatively constant throughout the filtration procedure.

Very rarely, if at all, are all of these criteria met during filtration. Several studies have concluded that cellulose acetate membrane filters (Millipore™), glass-fiber filters and silver filters do not satisfy the above requirements.[20,46,47] Generally, it is found that Nuclepore™ filters provide the best separation, although there are still material and methodological problems, as discussed below. In general, sizing of particles by filtration is poor in relation to the nominal pore size specifications. The poor performance of filters used in experimental settings has been reported by Logan[30] and Droppo et al.[43] Logan[30] has shown that as many as 8% of the number of particles and 50% of the mass can be retained on a 210 μm (pore diameter) polypropylene filter even though all of the particles were <100 μm. Likewise, Droppo et al.[43] have shown, for sequential filtration, errors as high as 60% of the sediment (by volume) isolated by filtration being below the targeted nominal pore size of the filters (60–10 μm nylon mesh). As such, the stated

nominal pore size cannot be used as a definitive cutoff for targeted size classes; however, further experimentation or modeling[30] may provide the user with an acceptable pore size and filter type for a given targeted size range.

As implied above, of all the methods of particle sizing, filtration is likely to be one of the most problematic and potentially inaccurate methods and yet if precautions are taken, and potential errors are realized, it can also be one of the most useful as it is one of the few methods in which particles can be physically separated into designated size classes for subsequent analysis. In addition, it lends itself to optical applications which can be very accurate and provide visual confirmation of particle size, composition and texture. The problems around filtration are based primarily on (a) the physical aspects of the filters, (b) the nature of the particles to be separated and (c) the procedure used for filtration. These problems and possible error controlling measures are discussed below.

4.1 Effect of Physical Aspects of Filter

The efficiency by which various filter types separate particles into targeted size classes based on their nominal pore size has most often been assessed with retention curves (Figure 8a–d). The size range covered by the plots represents the width of the pore size distribution, while the median pore size (the effective pore size) is represented by the 50% value. The steeper the slope of the line, the more selective the filter's performance is. Figure 8(a–d) suggests that Millipore™ and Whatman™ glass-fiber filters have the greatest selectivity with Nuclepore™ and Flotronics™ filters having poorer selectivity. Figure 9 shows that there are great differences between the effective pore size and the nominal pore size of the various filters as stated by the manufacturers. The Flotronics™ and Nuclepore™ membrane filters show a reasonably close 1:1 relationship (i.e. sharpest separation in the median pore size) whereas the Millipore™ (cellulose) filters showed similar effective pore sizes irrespective of the nominal pore size (i.e. poor separation at the median pore size) (the Whatman™ glass-fiber filters had effective pore sizes all below 1.0 μm). Given these results, glass-fiber and cellulose membrane filters are not recommended for separating particles by size.[30,46–48] This is primarily because fiber filters have a wide array of pore sizes and tortuous flow paths which result in the trapping of particles within the filter bed. Because Nuclepore™ filters act more like sieves, these appear to be the best filters for particle fractionation and grain size distribution analysis below 8 μm.[20,33,49] Nylon mesh such as Nitex™ can also be effective for larger particle size separation (see Table 1), although errors were also found by Droppo et al.[43] for these and Nuclepore™ filters. However, it should be realized, given that most retention curves for calibration purposes are based on measurements made with particle size standards or beads of known size, shape and density (to avoid the issue of aggregation), or on low-concentration highly defined natural samples, it is unlikely that the retention curves in Figure 8(a–d) bear any resemblance to a filter's performance when environmental/industrial flocculated cohesive particles are filtered. This is primarily related to increased pore clogging by such particles[20,30,43] (see below).

Filter clogging[20,30,43,49,50] is primarily a function of the nature of the filter (specifically material and pore structure) and of the nature of the particle (see below) and is probably the most significant problem associated with filtration in causing the greatest associated errors in particle sizing. As a filter becomes overloaded, fiber width increases and pore size decreases. For polycarbonate filters, clogging is initiated through surface coagulation and pore clogging by aggregates larger than the pore size. This has the effect of reducing the flow rate and increasing the removal efficiency by widening the band of particle selectivity (i.e. smaller particles are trapped). This problem can be to the extreme as "dissolved" and colloidal materials or elements can be removed by filtration.[48] Polycarbonate filters will clog faster than a cellulose membrane filter owing to their more defined singular pore structure. The problems of filter clogging can be avoided by stopping filtration at signs of reduced flow rate, by not reusing filters, using a larger diameter filter (larger surface area per unit volume filtered), by minimizing the volume of sample fractionated per filter, by diluting the sample to minimize particle–particle interactions (if chemically acceptable), by insuring a low flow rate and, if instrumentation allows, by keeping the sample above the filter stirred. (If bulk removal is the goal of the procedure, then filter clogging is not an issue.)

4.2 Effect of Nature of the Particles

Different particles will have different sticking coefficients[30] and the higher the coefficient the greater is the potential for surface coagulation and pore and fiber clogging. The importance of the sticking coefficient relative to filtration will vary depending on the filter material, the particle type (cohesive or non-cohesive) and solution characteristics such as ionic and organic concentrations.[30] The influence of particle type on filter performance is compounded by the majority of cohesive sediment generally existing in a flocculated state.[1,2] The rheology of flocculated sediment has been described as plastic, and, as such, flocs will deform (flatten) on

Figure 8 Retention curves for different types of filters. Each curve is labeled with the nominal pore size (μm) indicated by the manufacturer: (a) Millipore™ (cellulose ester depth filters); (b) Whatman™ (GFC GFA); (c) Nuclepore™ (polycarbonate); and (d) Flotronics™ (metal membrane). (Reproduced by permission of the American Society of Limnology and Oceanography from Sheldon.[47])

to the filter surface or into pores or fiber spacing, increasing the potential of filter clogging. If the filter is to be examined optically for the determination of particle size, then any deformation of the particles is undesirable. The use of plankton chambers, discussed in section 3.4, is recommended for providing an estimation of particle size distribution with a minimum of particle size distortion.

4.3 Effect of Procedure Used for Filtration

4.3.1 Effects of Sequential Filtration Procedure

Although there appears to be no significant difference in the resultant grain-size distribution derived between serial or parallel sample processing,[30] there are serious grain-size errors associated with the sequential filtering

Figure 9 Relationship between the effective pore size and the nominal pore size indicated by the manufacturer. (Reproduced by permission of the American Society of Limnology and Oceanography from Sheldon.[47])

of samples.[43] Droppo et al.[43] concluded from fractionation experiments with primary particle inorganic sediment that using the sequential filtration technique (irrespective of filter type) is very inaccurate as filters retain a spectrum of particles both larger and smaller than the targeted size classes (Figure 10a–f). In addition, the distribution errors observed are cumulative owing to the sequential nature of the process, thus further magnifying the error for successively smaller size classes. This is exemplified in Figure 10(a–f) where every size fractionation retained possesses a portion of particles which are $<8\,\mu m$. Such inaccuracies result in broader size distributions for each fractionated compartment and will have an erroneous influence on the mass in each size category, thus providing an erroneous size distribution. Modelling results by Logan[30] have shown that for sequential filtration with a wide range of screens and a glass-fiber filter <90% of particles (carboxylate microspheres) in any size class contributed to the actual size class defined by the nominal pore size of the screens/filters. For example, Logan[30] calculated that a $210\,\mu m$ nylon mesh would retain 50.1% of the total mass of particles even though none of the particles in the size distribution exceeded $100\,\mu m$. These errors are probably due to a number of possible factors, including sediment size, sediment and pore geometry, pore clogging, particle sticking coefficients, the flocculation and disaggregation process and instrumental assumptions of spherical particles. The error induced by pore clogging is accentuated as pore size decreases[20,43] and sticking coefficients increase.[30] Targeted size classes cannot be derived from the nominal pore sizes of the filters.

4.3.2 Effects of Sample Volume

While the amount of sediment to be filtered out of solution will be dictated by the analysis to be performed on the sediment, the smallest sample volume should be used in order to avoid overloading the filter, resulting in clogging and resultant inaccurate chemical and particle sizing as discussed in section 4.1.[20,47,48] When large-volume filtrations are needed, frequent filter changes and/or large area filters should be used.

4.3.3 Effects of Filter Pressure and Flow Rate

Although Sheldon[47] found that the degree of vacuum had no effect on the retention characteristics of various types of filters, a working rule when using filtration for particle size analysis is that, when possible, only gravity filtration should be performed. However, when positive or negative pressure is required, the lowest pressure or vacuum possible is preferred (below 0.17–0.3 atm).[20,47,49] In so doing, there is a minimization of the erroneous effects of particle breakup and deformation (flattening) at the filter surface[43,47] and filter clogging is also minimized by reducing the rate of particle trapping (especially by inertial collection).

The degree of vacuum or pressure is also related to the flow rate and, as such, a low flow rate is also desirable. This is particularly true for small particle sizes and colloids. Buffle et al.[20] have shown that for colloidal particles, there is a narrow window flow rate and storage time at which separation is optimized. If the flow rate is too fast (i.e. the residence time of the solution above the filter is too short), then variability in the particle sizing result is greater owing to filtration conditions and the nature of the membrane. If, on the other hand, the flow rate is too slow and the residence time too long, then variability is a function of storage conditions and particle nature.

4.3.4 Effect of Stirring

Whereas Laxen and Chandler[49] found that sample stirring had no benefits for Sartorius™ or Nuclepore™ filters, many have suggested that stirring the sample in the filtration reservoir while filtering helps to keep an even distribution of particles in suspension above the filter and reduces any concentration polarization that may occur between particles and the filter surface.[20,21] Stirring will have the greatest positive effect for the colloidal fraction of particles. If stirring is not applied then particles concentrate close to the filter surface and coagulation and associated filter clogging can occur at a faster rate.[48] Too

Figure 10 Distribution of particles for each targeted size class of a sequential filtration procedure: (a) >60; (b) 60–41; (c) 41–20; (d) 20–10; (e) 10–8; and (f) <8 μm. The vertical lines represent the nominal pore size of the applicable filters. The percentage of sediment finer than the nominal pore sizes is also indicated. (Reprinted with permission from I.G. Droppo, B.G. Krishnappan, S.S. Rao, E.D. Ongley, 'Investigation of a Sequential Filtration Technique for Particle Fractionation', *Environ. Sci. Technol.*, **29**, 546–550 (1995). Copyright 1995, American Chemical Society.)

much stirring can result in a change in particle size by promoting aggregation and/or disaggregation. Stirring, however, depending on the apparatus used, is not always possible.

4.3.5 Effect of Field Sampling

Filtering in the field, as opposed to filtering in the laboratory following sample transport/storage, will generally provide more accurate grain size results.[20,49] This is related to (a) minimizing aggregation within sample containers during storage and (b) minimizing chemical reactions brought about by changes in oxygen content, pH, ionic interactions and particle–particle interactions, which can affect the particle size distribution and chemical concentrations. This is primarily a result of precipitation, coprecipitation (often through oxidation) and adsorption

or desorption of ions. Sampling in the field is ideally suited to the direct observation of sediment by using plankton chambers as no sample manipulation is required (see section 3.4). Once the particles are at rest on the microscope slide, they do not move or distort and can then be transported to the laboratory for subsequent direct observation, microscopic analysis and imaging.

5 QUALITY ASSURANCE OF PARTICLE SEPARATION RESULTS

The quality assurance or validation of the accuracy of particle separation may be assessed through a number of technical procedures or through some simple approaches. Which approach to use is dependent on cost, availability of equipment, time of filtration and the nature of the experiment. As most artifacts from sample preparation, handling or filtration will result in an increase in the retention of particles on a filter, conditions which benefit the passage of solute and particles below the targeted size range should be considered as promoting the most realistic results. Buffle et al.[20] provide an excellent summation of the approaches that can be used to evaluate the reliability of filtration results. These are as follows:

1. *Flow-rate and Filtration Pressure*: flow rate and therefore filtration pressure should remain constant and independent of retention. Flow rate can be maintained at constant pressure by using a valve at the output of the cell.
2. *Stirring*: retention must be independent of stirring rate.
3. *Filtrate Concentration*: filtrate concentration should be constant during filtration as an indication of no filter clogging. This is one of the most effective methods of evaluating filtration as it is more qualitative than subjective visual inspection of filter caking.
4. *Microscopy*: microscopic examination of filters can be a very powerful tool in providing evidence of selectivity of filters relative to the grain size retained.
5. *Electrolyte Nature and Concentration*: although not discussed in this article [see Buffle et al.[20]] this may influence diverse processes relevant to filtration and therefore, separation results. Generalization of this effect is difficult and its effects should be tested for each application.

6 ALTERNATIVE PARTICLE SIZING BY OPTICAL IMAGE ANALYSIS

If the investigation only requires an accurate determination of grain size distribution, then filters can be observed through a standard microscope interfaced with an image analysis system. Such a method of particle sizing, however, has the potential to impart a number of artifacts within the results (although it is likely to be more accurate than that derived from mass-balance analysis using sequential filtration). These distribution artifacts arise from the following: (a) pressure filtration resulting in the deformation of flocculated particles either by disaggregation, aggregation, flattening or burying within pores; (b) particle morphological changes due to filter drying (drying of the particles (flocs) will result in morphological changes as many of these flocculated particles are over 90% water; as such, significant shrinkage can occur with concomitant influences on particle sizing results); and (c) particle morphological changes due to the need to make the filters transparent by the application of an oil such as paraffin or microscope immersion oil. Such an application of highly viscous material will in itself promote morphological changes and also a rehydration of particles with unknown effects. It is for these reasons that, if only a grain size distribution is required, the plankton chamber approach to particle sizing is preferred over filtration. The use of gravity settling on to the inverted microscope slide embedded within the plankton chamber allows the examination of particles in their natural state (hydrated) without the destructive manipulations possibly resulting from filtration. Furthermore, this technique allows the stabilization of flocs in agarose with minimal structural disturbance for their examination (single plankton chamber sample) by multiple microscopic techniques (conventional optical microscopy, scanning confocal laser microscopy and transmission electron microscopy).[44,51] Modification of particle structure in any way should always be avoided where possible as it will no doubt have a profound effect on particle size distributions or on other floc characteristics such as fractal dimensions.

DISCLAIMER

Information regarding equipment and the mention of trade names or commercial products are meant as a guide and should not be construed as an endorsement of any particular device or product.

ACKNOWLEDGMENTS

The author would like to thank Dr Gary Leppard for his insightful review of the manuscript. M. West performed the microscopy for the micrographs in Figure 4.

The use of classical, or time-averaged, light scattering methods to characterize the size and size distribution of macromolecules in dilute solutions or particles in dilute dispersions is discussed. The necessary scattering relations are presented systematically, starting with three cases at infinite dilution: the scattering extrapolated to zero angle, the scattering at small angle, and the scattering for arbitrary angle, including the inversion of the scattering data to estimate the size distribution. The relationships needed to effect an extrapolation to infinite dilution from data on dilute solutions are also discussed. These are followed by remarks on light scattering methods, and the concluding sections give examples for several applications. The Rayleigh–Gans–Debye (RGD) approximation is usually appropriate in the scattering from dilute polymer solutions and is also adequate for the scattering from dilute dispersions of small particles. The approximation is assumed when appropriate, but more complete theories are introduced where necessary, as in the use of the Mie–Lorentz theory for large spherical particles.

1 INTRODUCTION

Classical, or time-averaged, light scattering methods are well suited to characterizing certain properties of macromolecules in dilute solutions or particles in dilute dispersions. This technique goes under a variety of names, including static, elastic, integrated and absolute scattering. Information on the size and size distribution may be obtained, and in some cases, it may be possible to elucidate the shape of the macromolecule or particle. The theory and practice of such measurements is well represented in reviews and monographs,[1–24] providing the basis for this article. In addition to these, very useful compilations of original papers are available on the scattering from macromolecules[25] and particles.[26] In the following, the scattering relations are presented systematically, starting with three cases at infinite dilution: the scattering extrapolated to zero angle, the scattering at small angle, and the scattering for arbitrary angle. The relationships needed to effect an extrapolation to infinite dilution from data on dilute solutions are then discussed. Remarks on light scattering methods follow, and the concluding sections give examples of several applications. As discussed below, the RGD approximation is usually appropriate in scattering from dilute polymer solutions and is also adequate for scattering from dilute dispersions of small particles. It will be assumed for much of the following, but more complete theories will be introduced where necessary, as in the use of the Mie–Lorentz theory for large spherical particles.

2 SCATTERING RELATIONS

2.1 General Remarks

Classical, or static, light scattering refers to an experiment in which an intensity $I(\vartheta)$ is determined at a scattering angle ϑ by averaging the fluctuating intensity of the light scattered from a material over a time long compared with the timescale of the fluctuations.

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

The temporal character of the fluctuations is studied in dynamic light scattering,[1,6,10,17,27] (also see Chu,[7] p. 243) a subject outside the purview here. For dilute solutions of macromolecules, or dispersions of particles, the averaged intensity carries information on the intramolecular properties of the molecular weight M, mean-square radius of gyration R_G^2, and mean-square molecular optical anisotropy δ^2, as well as the intermolecular property of the second virial coefficient A_2, and possibly higher order virial coefficients and intermolecular interference phenomena. Furthermore, for polydisperse systems, the data may also permit assessment of any structural distribution (e.g. molecular weight, size, or possibly shape, of a dissolved molecule or dispersed particle). The reader should be forewarned that owing to its history and variety of applications, the nomenclature in light scattering varies among authors (e.g. see Kerker,[21] p. 60). In the interests of consistency, the nomenclature used herein will follow that used previously by the author,[1,4,10,18] and where appropriate these sources will be cited for further detail in addition to, or in lieu of, citations to the original literature referenced therein.

In general, it is not necessary to distinguish between solutions of macromolecules or dispersions of particles in discussing the fundamental relations for scattering, and the following applies to either case. For convenience, both macromolecules and particles will be referred to as the *solute*. In most experimental arrangements of interest here, the scattered intensity in the scattering plane, the plane containing the incident and scattered beams, is determined as a function of ϑ, or modulus $q = (4\pi/\lambda)\sin(\vartheta/2)$ of the scattering vector, with $\lambda = \lambda_0/n_{\text{medium}}$, where n_{medium} is the refractive index of the solution, λ_0 is the wavelength of the incident light in vacuo, and ϑ is the angle between the incident and scattered beams. Often, the electric vector of the incident light is plane polarized perpendicular to the scattering plane, and this arrangement will be presumed in the following, unless otherwise specified. The scattered light intensity is monitored through a photomultiplier or other photon-sensitive device, either as an analog signal or a digital photon count rate. In either case, an instrument response $G(\vartheta)$ at angle ϑ is determined, with $G(\vartheta)$ proportional to the time-averaged intensity $I(\vartheta)$ of the scattered light. The latter is used to compute the Rayleigh ratio $\mathbf{R}(\vartheta)$, given by $r^2 I(\vartheta)/VI_{\text{INC}}$, with r the distance between the scattering centers and the detector, V the scattering volume, and I_{INC} the intensity of the incident light; $\mathbf{R}(\vartheta)$ is often called the differential scattering cross-section in the physics literature (see Bohren and Huffman,[13] p. 383). The ratio $\mathbf{R}(\vartheta)/G(\vartheta)$ may be determined by an appropriate experiment for a given arrangement (also see Chu,[7] p. 243).[1,10,18] The following section will discuss the information that may be obtained in order to characterize the solute in a solution (or dispersion) by analysis of $\mathbf{R}(\vartheta)$ under various conditions.

The excess Rayleigh ratio for the solution with concentration c of solute, less that due to the solvent, is usually the property of interest. This is normally calculated as $\mathbf{R}_{\text{xs}}(\vartheta, c) = \mathbf{R}_{\text{SOLN}}(\vartheta, c) - \mathbf{R}_{\text{SOLVENT}}(\vartheta)$, but alternative estimates of $\mathbf{R}_{\text{xs}}(\vartheta, c)$ may be required for very low-molecular-weight solute.[28] The subscripts 'xs', etc. will be suppressed throughout, and $\mathbf{R}(\vartheta, c)$ will imply the excess quantity. Here, c is the weight of the solute per unit volume of the solution. Alternatively, the number of molecules ν per unit volume of the solution is sometimes used, especially in theoretical work; $\nu = cN_A/M_n$, with M_n the number average molecular weight determined, for example, from colligative properties, and N_A Avogadro's constant (see Flory,[29] p. 273). It may be noted that the scattered intensity in discussions of the scattering from particles is sometimes expressed in intensity units per particle per volume, with an implied factor ν omitted, for example these units are used in two well-known monographs focussed on the scattering from particles.[21,22]

The notation $\mathbf{R}_{\text{Si}}(\vartheta, c)$ will be used in the following to designate the polarization states of the scattered and incident light rays, where subscripts S and i will designate the polarization of the electric vectors of the scattered and incident light, respectively, relative to the scattering plane. Thus, for vertically polarized incident light, and horizontally or vertically polarized scattered light, respectively, the observed scattering may be expressed as Equations (1) and (2),[4,10]

$$\mathbf{R}_{\text{Hv}}(\vartheta, c) = \mathbf{R}_{\text{aniso}}(\vartheta, c) \tag{1}$$

$$\mathbf{R}_{\text{Vv}}(\vartheta, c) = \mathbf{R}_{\text{iso}}(\vartheta, c) + \left(\frac{4}{3}\right. \mathbf{R}_{\text{aniso}}(\vartheta, c) + \mathbf{R}_{\text{cross}}(\vartheta, c) \tag{2}$$

where $\mathbf{R}_{\text{Vv}}(\vartheta, c) = \mathbf{R}_{\text{iso}}(\vartheta, c)$ for an optically isotropic scatterer, and $\mathbf{R}_{\text{cross}}(\vartheta, c)$ is a cross-term that vanishes for an optically isotropic solute or for $\vartheta = 0$. The functions $\mathbf{R}_{\text{iso}}(\vartheta, c)$ and $\mathbf{R}_{\text{aniso}}(\vartheta, c)$ are discussed in the following sections. The Rayleigh ratio $\mathbf{R}_{\text{Hh}}(\vartheta, c)$ is discussed below, but in the RGD regime, $\mathbf{R}_{\text{Hh}}(\vartheta, c) = \mathbf{R}_{\text{Vv}}(\vartheta, c)\cos^2(\vartheta)$. In much of the older work, written prior to the advent of lasers as a commonly used source of the incident light, an unpolarized (or natural) incident beam is assumed, e.g. comprising equal components of plane-polarized light with electric vectors in the vertical and horizontal directions. Consequently, the Rayleigh ratio for light with electric vector in the vertical direction might be denoted $\mathbf{R}_{\text{Vu}}(\vartheta, c)$ in such a case, with $\mathbf{R}_{\text{Vu}}(\vartheta, c) = \mathbf{R}_{\text{Vv}}(\vartheta, c)/2$ for an isotropic solute (with $\mathbf{R}_{\text{Vh}}(\vartheta, c) = \mathbf{R}_{\text{Hv}}(\vartheta, c) = 0$) if the total intensity of the incident beam is used in the calculation of each.

In most of the discussion the RGD approximation will be assumed, but this constraint will be relaxed where necessary, e.g. in the use of the complete Mie–Lorentz scattering theory for large spheres (Bohren and Huffman,[13] p. 158; Kerker,[21] p. 414; van de Hulst,[22] p. 85). In the RGD approximation, the scatterer is treated as an assembly of scattering elements which scatter radiation independently of all other elements. The elements are taken to represent the smallest unit that both gives a unique refractive index tensor and for which interference effects are negligible for rays scattered from a single element, e.g. the elements are independent Rayleigh scatterers (see Chu,[7] p. 14; Bohren and Huffman,[13] p. 7; Kerker,[21] p. 414; van de Hulst,[22] p. 86).[16,18] An important property in the RGD approximation that is used in much of the following is that the optical contrast factor can usually be considered to be independent of the size or shape of the scatterer, depending only on its composition relative to that of the medium. This allows a factorization to be assumed in much of the following for which the RGD approximation is utilized, but which must be abandoned if that approximation cannot be used. Use of the RGD approximation greatly facilitates the discussion of the effects of heterogeneity of the scatterers, permitting analytical representations of certain averages for properties determined by analysis of $\mathbf{R}_{\mathrm{Vv}}(\vartheta, c)/c$ and $\mathbf{R}_{\mathrm{Hv}}(\vartheta, c)/c$, as discussed in the following. The RGD approximation fails as the phase shift of the light within an individual scatterer domain becomes too large, see below.

In most cases, the discussion will be couched in terms of the weight fraction $w_\mu = c_\mu/c$ of scattering components distinguished by some characteristic, e.g. molecular weight, shape, optical contrast relative to the supporting medium, etc. with overall concentration $c = \sum_\mu c_\mu$. As discussed below, $[\mathbf{R}_{\mathrm{Vv}}(\vartheta, c)/Mc]_\mu$ reduces to a constant under certain conditions, but in general, this ratio depends on M, c and ϑ, reflecting interference effects from the scattered rays from different scatterers, as well as the particular characteristics of the individual scatterer. Of course, similar expressions may be written for $\mathbf{R}_{\mathrm{Hv}}(\vartheta, c)$.

It is convenient to express $\mathbf{R}_{\mathrm{iso}}(\vartheta, c)$ in the form of Equations (3) and (4)[4,10]

$$\mathbf{R}_{\mathrm{iso}}(\vartheta, c) = K'\psi^2_{\mathrm{solute}} M_{\mathrm{LS}} S_{\mathrm{iso}}(\vartheta, c) c \tag{3}$$

$$S_{\mathrm{iso}}(\vartheta, c) = P_{\mathrm{iso}}(\vartheta, c) F_{\mathrm{iso}}(\vartheta, c) \tag{4}$$

where M_{LS} is the light scattering averaged molecular weight, $S_{\mathrm{iso}}(\vartheta, c)$ is the structure factor (see more below), $P_{\mathrm{iso}}(\vartheta, c)$ and $F_{\mathrm{iso}}(\vartheta, c)$ are intramolecular and intermolecular structure factors, respectively, with $P_{\mathrm{iso}}(0, c) = F_{\mathrm{iso}}(0, 0) = 1$, $K' = 4\pi^2 n^2_{\mathrm{medium}}/N_{\mathrm{A}}\lambda_0^4$, and ψ_{solute} a contrast factor; it should be noted that some authors use a notation in which $F_{\mathrm{iso}}(\vartheta, c)$ would be denoted $S_{\mathrm{iso}}(\vartheta, c)$.[30] For many cases discussed below, ψ_{solute} is equal to the refractive index increment $(\partial n/\partial c)_\Pi$ at osmotic equilibrium of solvent components.[10,16,18] For a solute in a single component solvent, $(\partial n/\partial c)_\Pi \approx n_{\mathrm{medium}}(\tilde{n} - 1)/\rho_{\mathrm{solute}}$, with ρ_{solute} the density of the solute, and $\tilde{n} = n_{\mathrm{solute}}/n_{\mathrm{medium}}$, where n_{solute} and n_{medium} are the refractive indices of the solute and medium, respectively.[31] This form is also used for a suspension of particles in a gas or vacuum for small $\tilde{n} - 1$; a revised expression for large $\tilde{n} - 1$ is discussed below (Bohren and Huffman,[13] p. 158; Kerker,[21] p. 414; van de Hulst,[22] p. 85). Here, and in the following, the subscript 'LS' designates the average obtained in light scattering for solute polydisperse in its properties. The nature of that average for particular types of heterogeneity is delineated in the following sections.

In general, for a nonabsorbing isotropic solution, expansion of $P_{\mathrm{iso}}(\vartheta, c)$ at infinite dilution gives Equation (5),[10,18] (see also Kerker,[21] p. 424; van de Hulst,[22] p. 98; Guinier and Fournet,[24] p. 24)

$$P_{\mathrm{iso}}(\vartheta, 0)^{-1} = 1 + \frac{(R^2_{\mathrm{G}})_{\mathrm{LS}} q^2}{3} + \cdots \tag{5}$$

where $(R^2_{\mathrm{G}})_{\mathrm{LS}}$ is the light scattering average mean-square radius of gyration of the scatterers and the notation $P_{\mathrm{iso}}(\vartheta, 0)$ denotes the function at infinite dilution. In most cases, for optically isotropic scatters, it is useful to express $F_{\mathrm{iso}}(\vartheta, c)$ as Equation (6)[4,10,31] (see also Yamakawa,[20] p. 186)

$$F_{\mathrm{iso}}(\vartheta, c)^{-1} = 1 + c\Gamma_{\mathrm{iso}}(c) P_{\mathrm{iso}}(\vartheta, c) H_{\mathrm{iso}}(\vartheta, c) \tag{6}$$

since in many cases, $H_{\mathrm{iso}}(\vartheta, c) \approx 1$. With this representation (Equation 7)

$$\begin{aligned} KcM/\mathbf{R}_{\mathrm{iso}}(\vartheta, c) &= S_{\mathrm{iso}}(\vartheta, c)^{-1} \\ &= P_{\mathrm{iso}}(\vartheta, c)^{-1} + c\Gamma_{\mathrm{iso}}(c) H_{\mathrm{iso}}(\vartheta, c) \end{aligned} \tag{7}$$

where $K = K'\psi^2_{\mathrm{solute}}$.

As elaborated below, in most cases, a virial expansion of $\Gamma_{\mathrm{iso}}(c)$ suffices for the scattering from dilute solutions (i.e. solutions with $cN_{\mathrm{A}}(R^2_{\mathrm{G}})^{3/2}_{\mathrm{LS}}/M_{\mathrm{LS}} \ll 1$), Equation (8)[4,10,31] (see also Yamakawa,[20] p. 186)

$$\Gamma_{\mathrm{iso}}(c) = 2(A_2)_{\mathrm{LS}} M_{\mathrm{LS}} + 3(A_3)_{\mathrm{LS}} M_{\mathrm{LS}} c + \cdots \tag{8}$$

with $(A_2)_{\mathrm{LS}}$ the light scattering averaged second virial coefficient, etc. The virial expansion may fail for charged scatterers in a solvent with very low ionic strength, so that electrostatic interactions are not shielded (see section 4 for examples),[10,16,18,32] and other forms for $\Gamma_{\mathrm{iso}}(c)$ may be required for moderately concentrated (or semidilute) solutions.[3,4,33] The general interpretation of the functions $P_{\mathrm{iso}}(\vartheta, c)$, $H_{\mathrm{iso}}(\vartheta, c)$ and the parameters M_{LS},

$(A_2)_{LS}$, and $(R_G^2)_{LS}$ may be complex for scatterers that are optically anisotropic or exhibit intramolecular and/or intermolecular heterogeneity.[10,18] These cases will be the subject of much of the following discussion. It should be noted that these relations and those to follow apply either to polymeric or colloidal solute, and that similar relations also obtain for the scattering of X-rays and neutrons (with revision of the definition for K),[34,35] with the principal experimental difference being the range of wavelength normally encompassed.

Similarly, $\mathbf{R}_{aniso}(\vartheta, c)$ may be expressed as Equation (9)[4,10]

$$\mathbf{R}_{aniso}(\vartheta, c) = \left(\frac{3}{5}\right) K'\gamma^2_{solute} \left(\frac{\delta}{\delta_0}\right)^2_{LS} M_{LS} S_{aniso}(\vartheta, c) c \quad (9)$$

where $(\delta/\delta_0)^2_{LS}$ is the light scattering averaged mean-square molecular optical anisotropy form factor, $S_{aniso}(\vartheta, c)$ is a structure factor, and γ_{solute} is an anisotropic contrast factor, conveniently expressed as $\psi_{solute}\delta_0$ if $\psi_{solute} \neq 0$, with δ_0 the optical anisotropy of a scattering element, see the section 4, ''Examples'' below.[10] As above, the factor $K'\gamma^2_{solute}$ must be modified if the RGD approximation is not valid. A similar set of expressions to those for $S_{iso}(\vartheta, c)$ may be written for $S_{aniso}(\vartheta, c)$, with $P_{iso}(\vartheta, c)$ replaced by $P_{aniso}(\vartheta, c)$, etc. In most cases of interest here, $\Gamma_{aniso}(c)$ is considerably smaller than $\Gamma_{iso}(c)$, $H_{aniso}(\vartheta, c) \approx 1$, and $P_{aniso}(\vartheta, c) \neq P_{iso}(\vartheta, c)$, except for $\vartheta = 0$,[10] see below.

2.2 Scattering at Zero Angle and Infinite Dilution

2.2.1 *Isotropic Solute in the Rayleigh–Gans–Debye Regime*

In this limit, attention is focused on $[\mathbf{R}_{Vv}(0, c)/c]^0$ (or $[\mathbf{R}_{Hv}(0, c)/c]^0$ below), with the implicit assumption that the extrapolations to zero angle and infinite dilution can be accomplished; these extrapolations are discussed in section 2.6. The superscript ''0'' indicates the extrapolation to infinite dilution throughout, and unless stated otherwise, it is assumed that $\psi_{solute} \neq 0$, as would usually be the case in applications of interest in light scattering. In this regime, $S_{iso}(\vartheta, c) = S_{aniso}(\vartheta, c) = 1$, simplifying the analysis. For example, $[\mathbf{R}_{Vv}(0, c)/K'\psi^2_{solute}c]^0$ is equal to the parameter M_{LS}, which as seen below, may be equal to the weight-average molecular weight M_w under certain conditions, but will often be a more complex function of the properties of the scatterers. Beginning within the RGD approximation, for an optically isotropic solute comprising a number of components, possibly differing in chemical composition, Equations (10) and (11) apply[10,18]

$$M_{LS} = \left(\frac{\mathbf{R}_{Vv}(0, c)}{K'\psi^2_{solute}c}\right)^0 \quad (10)$$

$$M_{LS} = \frac{\sum_\mu w_\mu M_\mu^{-1} \left(\sum_i \psi_i m_i\right)^2_\mu}{\psi^2_{solute}} \quad (11)$$

with ψ_i and m_i the refractive index increment and the molar mass of element i, respectively, and w_μ the weight fraction of components with molecular weight $M_\mu = (\quad m_i)_\mu$ and identical values of $(\quad \psi_i m_i)_\mu$, with $\psi_{solute} = \quad w_\mu\psi_\mu$. Here, the sums over i extend over all of the scattering elements in molecule (particle) μ.

If each component is compositionally homogeneous, i.e. has only one type of scattering element, then $(\quad \psi_i m_i)_\mu = \psi_\mu M_\mu$, and Equation (12) follows

$$M_{LS} = \frac{\sum_\mu w_\mu M_\mu \psi^2_\mu}{\psi^2_{solute}} \quad (12)$$

In the simplest case, for an optically isotropic, compositionally homogeneous solute, $\psi_\mu = \psi_{solute}$, and this reduces to the well-known relation, Equation (13)[10,18,31]

$$M_{LS} = M_w = \sum_\mu w_\mu M_\mu \quad (13)$$

where w_μ is the weight fraction of component μ with molecular weight M_μ. This simple relation applies to solutions or dispersions in a mixed solvent, provided that $(\partial n/\partial c)_\Pi$ is used, as stipulated above. If the refractive index $(\partial n/\partial c)_w$ determined at constant composition of the mixed solvent is used instead, then, to a good approximation, Equation (14) holds[10,16,18]

$$M_{LS} = \left(\frac{(\partial n/\partial c)_\Pi}{(\partial n/\partial c)_w}\right)^2 M_w \quad (14)$$

where $(\partial n/\partial c)_\Pi = (\partial n/\partial c)_w$ for a single-component solvent. The ratio $(\partial n/\partial c)_\Pi/(\partial n/\partial c)_w$ may be interpreted in terms of preferential solvation of the solute by a component of the solvent.[10,16,18] Deviations of $(\partial n/\partial c)_\Pi/(\partial n/\partial c)_w$ from unity are usually most pronounced when the preferentially solvating component is present at low concentration in the mixed solvent.

The more complex relation given above must be used if the solute is optically heterogeneous, as with a copolymer or particles with a spatially varying refractive index. For the special case with only two types of element, characterized by refractive index increments ψ_A and ψ_B, with $\psi_{solute} = w_A\psi_A + (1 - w_A)\psi_B \neq 0$, Equation (15) applies[10,36,37]

$$M_{LS} = M_w + 2Y \sum w_\mu M_\mu \Delta w_\mu + Y^2 \sum w_\mu M_\mu (\Delta w_\mu)^2 \quad (15)$$

where $\Delta w_\mu = (w_A)_\mu - w_A = w_B - (w_B)_\mu$ and $Y = (\psi_A - \psi_B)/\psi_{solute}$. Thus, M_{LS} is expected to be parabolic in

Y, with $M_{LS} = M_w$ for $Y = 0$. Since $\Delta w_\mu = 0$ for either a strictly alternating copolymer, or a copolymer with random placement of the monomers, $M_{LS} = M_w$ for these important cases. Similarly, $M_{LS} = M_w$ for a collection of particles with two kinds of scattering element, provided that the composition of each particle is identical to the average composition.

2.2.2 *Isotropic Solute Beyond the Rayleigh–Gans–Debye Regime*

It should be recognized at the outset that the RGD approximation will almost always be adequate for (nonabsorbing) threadlike macromolecules (e.g. flexible or semiflexible coils, rod-like or helical chains, etc.). This is the case not only at zero angle and infinite dilution, but also for all angles and dilute solutions, owing to the sparse density of the macromolecule in the intramolecular "domain". Thus, the RGD approximation may be applied, even for a large macromolecule, with an appreciably different refractive index to that of the solvent. The failure of the RGD approximation arises for large particles, under certain conditions elaborated in the following. If the RGD approximation cannot be used, the $[\mathbf{R}_{Vv}(0, c)/K'\psi^2_{solute}]^0_\mu$ may still be computed using an appropriate model, but because the scattering may no longer be taken as a sum over independent Rayleigh scattering elements, $\left(\psi_i m_i\right)_\mu$ for the μ-th scatterer must be replaced by a more complex function. For the discussion of M_{LS}, this can be done for compositionally homogeneous scatterers by including a factor $h(\tilde{n}_\mu)$ in ψ_μ for the μ-th scattering component, and multiplication of the modified ψ_μ by a function $m(\tilde{n}_\mu, \lambda, M_\mu)$. Thus, even for chemically homogeneous scatterers differing only in size, the contrast factor may depend significantly on λ, $\tilde{n}$, M_μ, and the shape of the scatterer. With this modification, $M_{LS} = [m(\tilde{n}, \lambda, M)]^2 M$ for a monodisperse solute (with M_{LS} calculated using ψ_μ including the factor $h(\tilde{n}_\mu)$). For example, with the Mie theory for a homogeneous sphere $h(\tilde{n})$ is given by $h_{sph}(\tilde{n}) = 3(\tilde{n} + 1)/2(\tilde{n}^2 + 2)$ (see Bohren and Huffman,[13] p. 158; Kerker,[21] p. 414; van de Hulst,[22] p. 70) and $m(\tilde{n}, \lambda, M)$ may be expressed as $m_{sph}(\tilde{n}, \alpha)$, and calculated as a function of $\tilde{n}$ and $\alpha = 2\pi R/\lambda$; $m_{sph}(\tilde{n}, \alpha)$ reduces to unity as the magnitude of the maximum phase shift $2\alpha|\tilde{n} - 1|$ in the particle becomes small (see Bohren and Huffman,[13] p. 113; Kerker,[21] p. 91; van de Hulst,[22] p. 127). Examples of $M_{LS}/M = [m_{sph}(\tilde{n}, \alpha)]^2$ for monodisperse spheres given in Figure 1 over a range of $\tilde{n}$ and α reveal the complex character of this function, with the possibility that M_{LS}/M may be either larger or smaller than unity. In the use of this figure, consistency is required between M obtained from the determined M_{LS} and the ratio M_{LS}/M and $R = (3M/4\pi\rho N_A)^{1/3}$ used to select α, where ρ is the density of the particle. Deviation of M_{LS}/M from unity is important, for example, in the analysis of the eluent from chromatographic columns by low angle light scattering for large particles, see section 4 below.

It may be noted that the Rayleigh ratio is often not mentioned explicitly in discussions involving the Mie theory, but rather, the theory is developed in terms of scattering amplitude functions $S_i(\vartheta)$, which are the components of the scattering tensor for the scattering from an individual scatterer (see Bohren and Huffman,[13] p. 65; Kerker,[21] p. 47; van de Hulst,[22] p. 47); $S_i(\vartheta)$ is not to be confused with the structure factor $S(\vartheta, c)$ defined above. Reduced intensity functions are computed from the $S_i(\vartheta)$, e.g. for nonabsorbing, optically isotropic scatterers, $i_{Vv}(\vartheta) = |S_1(\vartheta)|^2$ and $i_{Hh}(\vartheta) = |S_2(\vartheta)|^2$, with $[\mathbf{R}_{Vv}(\vartheta, c)/\nu]^0 = N_A i_{Vv}(\vartheta)/k^2$, etc. where $k = 2\pi/\lambda$. For example, $i_{Vv}(\vartheta) = i_{Vv}(0)P_{Vv}(\vartheta, 0)$, with $i_{Vv}(0) = \alpha^6\{2(\tilde{n} - 1)h_{sph}(\tilde{n})/3\}^2[m_{sph}(\tilde{n}, \alpha)]^2$ for spherical particles in the nomenclature used here, which reduces to the expected result $[\mathbf{R}_{Vv}(\vartheta, c)/c]^0 = K'\psi^2_{solute}M_{LS}$ for this case (including the factor $h_{sph}(\tilde{n})$ in ψ_{solute}).

For isotropic spheres, functions in the Mie theory may be expanded for $\tilde{n}\alpha \leq 1$ to give a result (see van de Hulst,[22] p. 45) that may be cast in the form of Equations (16) and (17)

$$m_{sph}(\tilde{n}, \alpha) = 1 + j_{sph}(\tilde{n})\alpha^2|\tilde{n} - 1| + \cdots \tag{16}$$

$$j_{sph}(\tilde{n}) = \frac{(\tilde{n} + 1)(\tilde{n}^4 + 27\tilde{n}^2 + 38)}{[15(\tilde{n}^2 + 2)(2\tilde{n}^2 + 3)]} \tag{17}$$

for nonabsorbing monodisperse spheres, where $j_{sph}(\tilde{n})$ approaches 44/75 as $\tilde{n}$ tends to unity. As may be seen in Figure 1, this expression provides a useful fit to $m_{sph}(\tilde{n}, \alpha)$ for small $\alpha^2|\tilde{n} - 1|$, but is generally limited to $\alpha^2|\tilde{n} - 1| < 0.1$ and $\alpha < 1$. In principle, in this range, the deviation from the RGD approximation could be taken into account using the above in expressions for M_{LS} discussed below for the scattering from spheres heterogeneous in M.

For nonabsorbing spheres with $\alpha \gg 1$, $i_{Vv}(0) = k^2[\mathbf{R}_{Vv}(0, c)/\nu]^0/N_A$ is closely approximated by $\{(\alpha^2/4)Q_{sca}(\tilde{n}, \alpha)\}^2$,[38] (see also Kerker,[21] p. 91) where $Q_{sca}(\tilde{n}, \alpha)$ is the extinction efficiency for scattering for spheres at infinite dilution, i.e. $\exp(-\tau\nu b)$ is the fraction of the incident light transmitted through a sample with turbidity $\tau = Q_{sca}(\tilde{n}, \alpha)\pi R^2$, thickness b and concentration ν. Numerical calculations show that the approximation is quite reasonable for $\tilde{n} > 1.3$ and $\alpha > 4$, with the minimum value of α for which the approximation is useful decreasing with increasing $\tilde{n}$. The abundant literature on the extinction efficiency provides a means to compute $m_{sph}(\tilde{n}, \alpha)$ in this range and has itself been discussed as a means of characterizing size heterogeneity among spherical solutes (see Kerker,[21] p. 351).[39] For example,

Figure 1 Ratio M_{LS}/M ($= m_{sph}(\tilde{n}, \alpha)^2$) of the light scattering averaged molecular weight M_{LS} for monodisperse spheres of radius R to the molecular weight M as a function of the relative refractive index $\tilde{n}$ for the indicated values of the size parameter $\alpha = 2\pi R/\lambda$. The dashed lines give the limiting behavior for small $\tilde{n} - 1$ (see Equations 16 and 17).

$Q_{sca}(\tilde{n}, \alpha) = (32/27)\alpha^4|\tilde{n} - 1|^2$ for Rayleigh scattering, increasing to $Q_{sca}(\tilde{n}, \alpha) = 2$ in the Fraunhofer scattering regime ($\alpha \gg 1$ and $\tilde{n} > 1.1$) discussed more extensively in the following (see van de Hulst,[22] p. 131).

For a polydisperse nonabsorbing solute, with all components having identical $\tilde{n}$, Equation (18) applies

$$M_{LS} = \sum_{\mu} w_\mu M_\mu [m(\tilde{n}, \lambda, M_\mu)]^2 \qquad (18)$$

Similar expressions could be obtained for particles of other shape for which the RGD approximation cannot be used. For a spherical solute, use of $m(\tilde{n}, \lambda, M_\mu) = m_{sph}(\tilde{n}, \alpha_\mu)$ gives $M_{LS} \geq M_w$, but M_{LS} cannot generally be reduced to an expression involving standard average molecular weights. In the limited range with $\tilde{n}\alpha_\mu < 1$ discussed above, the approximate expression for $m_{sph}(\tilde{n}, \alpha)$ may be applied, with the result (for particles of homogeneous refractive index, Equation 19)

$$M_{LS} \approx M_w + 2\left(\frac{2\pi R}{\lambda M^{1/3}}\right)^2 j(\tilde{n})|\tilde{n} - 1|M_{(5/3)}^{5/3} \qquad (19)$$

where $M_{(5/3)}^{5/3} \approx M_z^{2/3} M_w$ is defined in Table 1 (for $\varepsilon = 2/3$). In principle, the dependence on λ embodied in the parameters α_μ provides a means of interpreting M_{LS} (or equivalently, Q_{sca}) in terms of w_μ from the variation of M_{LS} with λ using the Mie theory to compute $m_{sph}(\tilde{n}, \alpha)$, after accounting for any dispersion in the refractive indices of solute or solvent. Such a procedure has been the basis of some methods proposed in the literature for characterizing the size of spheres by transmission measurements (see Bohren and Huffman,[13] p. 287; Kerker,[21] p. 325),[39] but these have been largely superseded by methods discussed in the following involving measurements over a range of scattering angles.

2.2.3 *Anisotropic Solute*

For a solute with anisotropic scattering elements, in the RGD regime $[\mathbf{R}_{Hv}(0, c)/K'\psi_{solute}^2 c]^0$ gives the light scattering averaged mean-square molecular anisotropy δ_{LS}^2 (with $\psi_{solute} \neq 0$), Equation (20):[10,40,41]

$$\frac{\mathbf{R}_{Hv}(0, c)}{K'\psi_{solute}^2 c}^0 = \left(\frac{3}{5}\right) M_{LS}\delta_{LS}^2 \qquad (20)$$

Table 1 Light scattering average mean-square radius of gyration and hydrodynamic radius (RGD approximation)

	$(R_G^2)_{LS}$	$(R_H)_{LS}$
Exact relation[a]	$(1/M_w) \quad w_\mu M_\mu (R_G^2)_\mu$	$M_w \quad w_\mu M_\mu (R_H^{-1})_\mu$
Approximation for[b] $R_H \propto R_G \propto M^{\varepsilon/2}$	$(R_G^2/M^\varepsilon)M_{(\varepsilon+1)}^{\varepsilon+1}/M_w$	$(R_H/M^{\varepsilon/2})M_w/M_{(1-\varepsilon/2)}^{1-\varepsilon/2}$
Random-flight coil;[c] $\varepsilon = 1$	$(R_G^2/M)M_z$	$(R_H/M^{1/2})M_w/M_{(1/2)}^{1/2} \approx (R_H/M^{1/2})M_w^{1/2}(M_w/M_n)^{0.10}$
Rod-like chain;[c] $\varepsilon \approx 2$	$(R_G^2/M^2)M_z M_{z+1}$	$(R_H/M)M_w$
Sphere;[c] $\varepsilon = 2/3$	$(R_G^2/M^{2/3})M_{(5/3)}^{5/3}/M_w \approx (R_G^2/M^{2/3})M_z^{2/3}(M_w/M_z)^{0.10}$	$(R_H/M^{1/3})M_w/M_{(2/3)}^{2/3} \approx (R_H/M^{1/3})M_w^{1/3}(M_w/M_n)^{0.10}$

[a] For optically isotropic solute, and with $\partial n/\partial c$ the same for all scattering elements.

[b] $M_{(\alpha)} = \left(\sum_\mu w_\mu M_\mu^\alpha\right)^{1/\alpha}$ and $M_n = 1 \Big/ \sum_\mu w_\mu M_\mu^{-1}$; $M_w = \sum_\mu w_\mu M_\mu$; $M_z = \sum_\mu w_\mu M_\mu^2 \Big/ \sum_\mu w_\mu M_\mu$.

[c] Approximations are for a solute with a Schulz–Zimm (two-parameter exponential) distribution of M, for which $M_{(\alpha)} \approx M_w\{\Gamma(1 + h + \alpha)/\Gamma(1 + h)\}^{1/\alpha}/(1 + h)$, where $h^{-1} = (M_w/M_n)^{-1}$, see Berry.[42]

For solute with identical, but optically anisotropic scattering elements, $M_{LS} = M_w$, and Equation (21) applies

$$\delta^2_{LS} = \sum_\mu \frac{w_\mu M_\mu \delta^2_\mu}{M_w} \tag{21}$$

Since δ^2_{LS} arises from orientational correlations among the scattering elements, it cannot be interpreted in the absence of a structural model for the scatterer. An example is included below. The expression for $[\mathbf{R}_{Vv}(0,c)/K'\psi^2_{solute}c]^0$ for this case becomes (Equation 22)[10]

$$\left[\frac{\mathbf{R}_{Vv}(0,c)}{K'\psi^2_{solute}c}\right]^0 = M_{LS}\left\{1 + \frac{4\delta^2_{LS}}{5}\right\} \tag{22}$$

2.3 Scattering at Small Angle and Infinite Dilution

2.3.1 Isotropic Solute in the Rayleigh–Gans–Debye Regime

The ambiguous term *small angle* indicates that ϑ is small enough that the parameter $(R^2_G)_{LS}$ defined by the equivalent expressions, Equation (23)

$$\frac{(R^2_G)_{LS}}{3} = \left[\frac{c}{\mathbf{R}_{Vv}(0,c)}\right]^0 \Bigg\}^{-1} \frac{\partial[c/\mathbf{R}_{Vv}(\vartheta,c)]^0}{\partial q^2} = \frac{\partial \ln[\mathbf{R}_{Vv}(\vartheta,c)/c]^0}{\partial q^2} \tag{23}$$

may be determined in the limit as ϑ goes to zero, where the superscript "0" indicates that the data are extrapolated to infinite dilution. Thus, for optically isotropic scattering elements, the expansion give above for $P_{iso}(\vartheta,0)^{-1}$ may be applied, so that at infinite dilution (averaged over all orientations of the scatterers), in the RGD approximation, Equation (24) follows[1,10,18]

$$(R^2_G)_{LS} = \sum_\mu w_\mu M_\mu^{-1} \frac{\sum\sum_{ij} \psi_i m_i \psi_j m_j \langle r^2_{ij}\rangle}{2M_{LS}\psi^2_{solute}}{}_\mu \tag{24}$$

where $\langle r^2_{ij}\rangle$ is the mean-square separation of scattering elements i and j, and $\psi_{solute} \neq 0$. In this expression, w_μ is the weight fraction of a component with molecular weight M_μ and common ($\psi_i m_i \psi_j m_j \langle r^2_{ij}\rangle)_\mu$, as scatterers with a given molecular weight may differ in composition and/or shape.

For a solute comprising optically identical scattering elements in all components (in the RGD approximation), Equation (25)

$$(R^2_G)_{LS} = \sum_\mu w_\mu M_\mu \frac{\sum\sum_{ij} \langle r^2_{ij}\rangle}{2M_w}{}_\mu = \sum_\mu w_\mu M_\mu \frac{(R^2_G)_\mu}{M_w} \tag{25}$$

where again, the ensemble may include chains with identical M_μ but different $(R^2_G)_\mu$, as for a collection of branched and linear chains, all with the same molecular weight. The similarity between this and the expression for the z-average molecular weight (obtained by replacing $(R^2_G)_\mu$ by M_μ) often motivates the notation $(R^2_G)_z$ for $(R^2_G)_{LS}$ (or Φ_z for any property Φ_μ similarly averaged), but that notation may be misleading if $(R^2_G)_\mu$ is not proportional to M_μ, and is not employed here. The parameter R^2_G may be related to the characteristics of the scatterer in this RGD regime, such as the contour length L and persistence length $\hat{a}$ of polymer chains, the radius R of spheres, etc. (see Table 1), or, in some cases, expressed as a power of the molecular weight of the scatterer. Thus, for a solute with the special property that $(R^2_G)_\mu = rM^\varepsilon_\mu$ with r a constant, the summation gives Equations (26) and (27)[1,42]

$$(R^2_G)_{LS} = \frac{rM_{(\varepsilon+1)}^{\varepsilon+1}}{M_w} \tag{26}$$

$$M_{(\alpha)} = \left(\sum_\mu w_\mu M^\alpha_\mu\right)^{1/\alpha} \tag{27}$$

where expressions for $M_{(\alpha)}$ are given in Berry[42] for a number of commonly used molecular-weight distributions (e.g. although $M_{(-1)} = M_n$, $M_{(1)} = M_w$, $M_{(2)} = (M_w M_z)^{1/2}$ such simple expressions are not possible if α is not an integer). Expressions for $(R^2_G)_{LS}$ are given in Table 1 for a few cases of interest.

Values of the light scattering averaged hydrodynamic radius $(R_H)_{LS}$ determined by dynamic light scattering are included in Table 1 for comparison. For example, for a random-flight chain ($\varepsilon = 1$), $(R^2_G)_{LS} = rM_z$, with $r = \hat{a}L/3M$, and for a rod ($\varepsilon = 2$), $(R^2_G)_{LS} = rM_zM_{z+1}$, with $r = (L/M)^2/12$, where M_z and M_{z+1} are the z- and $z+1$-average molecular weights. It may be noted that in general, the averages in $(R^2_G)_{LS}$ and $(R_H)_{LS}$ differ.

For an optically isotropic solute discussed above comprising two different types of scattering elements (with $\psi_{solute} \neq 0$, and in the RGD approximation, Equation 28),[10,36,37]

$$(R^2_G)_{LS} = x(R^2_G)_A + (1-x)(R^2_G)_B + x(1-x)\Delta^2_{AB} \tag{28}$$

for a sample monodisperse in molecular weight, with $x = w_A\psi_A/\psi_{solute}$, $(R^2_G)_A$ and $(R^2_G)_B$ the mean-square

radii of gyration of the portions of the solute molecules (particles) comprising only type A and type B scattering elements, respectively, and Δ^2_{AB} the mean-square separation of the center of mass for these portions. The possible dependence of the parameters $(R^2_G)_A$, $(R^2_G)_B$ and Δ^2_{AB} on solvent is neglected herein; this would be expected to be less of an issue with particles than with polymer chains. Expressions are available for Δ^2_{AB} for certain graft copolymers, and for a solute polydisperse in molecular weight.[36] In some cases Δ^2_{AB} is zero, simplifying the expression for $(R^2_G)_{LS}$, i.e. alternating copolymers or copolymers with a random placement of monomers, or spheres with a uniform coating (or shell). For block copolymers comprising n blocks each of A and B chains (e.g. $n = 1$ for an AB-diblock copolymer), $\Delta^2_{AB} = 2\{(R^2_G)_A + (R^2_G)_B\}/n$, showing that Δ^2_{AB} decreases with increasing n, as expected since $(R^2_G)_{LS} = (R^2_G)_A = (R^2_G)_B$ for an alternating copolymer.[36] Inspection of these expressions shows that $(R^2_G)_{LS}$ may bear little resemblance to the geometric mean-square radius of gyration $(R^2_G)_{geo}$ of the chain, e.g. $(R^2_G)_{LS}$ may be negative, whereas$(R^2_G)_{geo} > 0$. For example, one could construct a diblock polymer or a coated sphere for which $(R^2_G)_{LS}$ is zero, or even negative, though $(R^2_G)_{geo}$ must be positive, see section 4 examples below.

2.3.2 *Isotropic Solute Beyond the Rayleigh–Gans–Debye Regime*

The preceding expressions must be modified if the RGD approximation fails, as the basic assumption in the RGD model that the scattering from the elements may be added independently for a particle is no longer valid (the reader is reminded that as discussed above, the RGD approximation is almost always adequate for (nonabsorbing) thread-like macromolecules). For a compositionally homogeneous scatterer (all particles with the same $\tilde{n}$), Equation (29) applies

$$(R^2_G)_{LS} = \frac{\sum_\mu w_\mu M_\mu y(\tilde{n}, \lambda, M_\mu)[m(\tilde{n}, \lambda, M_\mu)]^2 (R^2_G)^{(RGD)}_\mu}{\sum_\mu w_\mu M_\mu [m(\tilde{n}, \lambda, M_\mu)]^2} \tag{29}$$

where $(R^2_G)^{(RGD)}_\mu$ is the value in the RGD regime, $m(\tilde{n}, \lambda, M_\mu)$ is defined above, and $y(\tilde{n}, \lambda, M_\mu)$ tends to unity as $\alpha|\tilde{n} - 1|$ tends to zero.

With the Mie theory for a compositionally homogeneous sphere, for which $(R^2_G)^{(RGD)} = 3R^2/5$, $y(\tilde{n}, \lambda, M)$ may be expressed as $y_{sph}(\tilde{n}, \alpha)$, and calculated as a function of $\tilde{n}$ and $\alpha = 2\pi R/\lambda$ (see Bohren and Huffman,[13] p. 113; Kerker,[21] p. 91; van de Hulst,[22] p. 127). Consequently, for monodisperse spheres, Equation (30) applies

Figure 2 Ratio $(R^2_G)_{LS}/(3R^2/5)(=y_{sph}(\tilde{n}, \alpha))$ of the light scattering averaged mean-square radius of gyration $(R^2_G)_{LS}$ for monodisperse spheres of radius R to the geometric square radius of gyration as a function of (a) the size parameter $\alpha = 2\pi R/\lambda$ for the indicated values of the relative refractive index $\tilde{n}$, and (b) the relative refractive index $\tilde{n}$ for the indicated values of the size parameter $\alpha = 2\pi R/\lambda$.

$$(R^2_G)_{LS} = \left(\frac{3}{5}\right. \quad y_{sph}(\tilde{n}, \alpha)R^2 \tag{30}$$

Examples of $(R^2_G)_{LS}/\{3R^2/5\} = y_{sph}(\tilde{n}, \alpha)$ are shown in Figure 2 over a range of $\tilde{n}$ and α, showing the complex character of this function. Expansion of $y_{sph}(\tilde{n}, \alpha)$ for $\tilde{n}\alpha \leq 1$ gives a result (van de Hulst,[22] p. 45) that may be cast in the form, $y_{sph}(\tilde{n}, \alpha) \approx p_{sph}(\tilde{n}) = (\tilde{n}^2 + 2)(\tilde{n}^2 + 4)/[3(2\tilde{n}^2 + 3)]$, where $p_{sph}(\tilde{n})$ approaches unity as $\tilde{n}$ tends to unity, so that $(R^2_G)_{LS} = 3R^2/5$ as $\tilde{n}$ tends to unity and $\tilde{n}\alpha \ll 1$, as expected in the RGD regime. It may be noted that even if $\alpha \ll 1$, so that $m_{sph}(\tilde{n}, \alpha) \approx 1$ and $y_{sph}(\tilde{n}, \alpha) \approx p_{sph}(\tilde{n})$, $(R^2_G)_{LS}$ tends to $\tilde{n}^2R^2/10$ for $\tilde{n} \gg 1$ (but $\tilde{n}\alpha \leq 1$). The dependence on $\tilde{n}$ for small α is most clearly seen in Figure 2(a); the fit of this approximate relation is good for $\alpha < 1$. Since $(R^2_G)_{LS} = 3R^2/4$, independent of $\tilde{n}$, in the Fraunhofer scattering regime ($\alpha \gg 1$ and $\tilde{n} \gg 1$) discussed in the next

section (see Kerker,[21] p. 325),[43,44] $y_{\mathrm{sph}}(\tilde{n}, \alpha)$ tends to 5/4 in that limit; the values of α used in Figure 2 are too small to exhibit such behavior. Similar expressions could be developed for other particles to which the Mie theory has been applied, e.g. stratified spheres and related structures mentioned in the preceding (see Bohren and Huffman,[13] p. 475).[45,46]

As may be seen in Figure 2, the transition from the behavior for $\tilde{n} \approx 1$ and $\tilde{n}\alpha \ll 1$ to that for $\alpha \gg 1$, for any $\tilde{n}$, is complex, prohibiting an analytic representation of $(R_{\mathrm{G}}^2)_{\mathrm{LS}}$ for a sample of unknown size distribution. Thus, although Equation (31)

$$(R_{\mathrm{G}}^2)_{\mathrm{LS}} = \left(\frac{3}{5}\right) \frac{\sum_{\mu} w_\mu M_\mu y_{\mathrm{sph}}(\tilde{n}, \alpha_\mu)[m_{\mathrm{sph}}(\tilde{n}, \alpha_\mu)]^2 R_\mu^2}{\sum_{\mu} w_\mu M_\mu [m_{\mathrm{sph}}(\tilde{n}, \alpha_\mu)]^2} \tag{31}$$

holds for a collection of spheres of different size, but identical $\tilde{n}$, this cannot generally be reduced to an expression involving standard average molecular weights. In principle, assuming that both $(R_{\mathrm{G}}^2)_{\mathrm{LS}}$ and M_{LS} can be determined (which may be difficult for large particles), one could compare these with values of $(R_{\mathrm{G}}^2)_{\mathrm{LS}}$ and M_{LS} calculated with an assumed two-parameter distribution function of M as a means to characterize the size distribution, e.g. for spheres, using the Mie theory to compute $y(\tilde{n}, \lambda, M_\mu) = y_{\mathrm{sph}}(\tilde{n}, \alpha_\mu)$ and $m(\tilde{n}, \lambda, M_\mu) = m_{\mathrm{sph}}(\tilde{n}, \alpha_\mu)$. In essence, a similar strategy is adopted by methods that attempt to fit the scattering determined at two small scattering angles (see Kerker,[21] p. 351).[44] In addition, in principle, the dependence on λ embodied in the parameters α_μ provides a means of interpreting $(R_{\mathrm{G}}^2)_{\mathrm{LS}}$ in terms of w_μ from the variation of $(R_{\mathrm{G}}^2)_{\mathrm{LS}}$ with λ using the Mie theory to compute $y_{\mathrm{sph}}(\tilde{n}, \alpha_\mu)$ and $m_{\mathrm{sph}}(\tilde{n}, \alpha_\mu)$, after accounting for any dispersion in the refractive indices of solute or solvent.

2.3.3 Anisotropic Solute

An estimate for $(R_{\mathrm{G}}^2)_{\mathrm{LS}}$ may be obtained from the dependence of either $[K'c/\mathbf{R}_{\mathrm{Vv}}(\vartheta, c)]^0$ or $[K'c/\mathbf{R}_{\mathrm{Hv}}(\vartheta, c)]^0$ for the scattering from anisotropic solutes in the RGD regime. Thus, for a solute with identical scattering elements, expressions for semiflexible chains give Equations (32) and (33),[10,41,47–49]

$$P_{\mathrm{Vv}}(\vartheta, 0)^{-1} = 1 + \frac{[J_{\mathrm{Vv}}(\delta) R_{\mathrm{G}}^2]_{\mathrm{LS}} q^2}{3 + \cdots} \tag{32}$$

$$P_{\mathrm{Hv}}(\vartheta, 0)^{-1} = 1 + \frac{3[J_{\mathrm{Hv}}(\delta) R_{\mathrm{G}}^2]_{\mathrm{LS}} q^2}{7 + \cdots} \tag{33}$$

Expressions for $[J_{\mathrm{Vv}}(\delta) R_{\mathrm{G}}^2]_{\mathrm{LS}}$ and $[J_{\mathrm{Hv}}(\delta) R_{\mathrm{G}}^2]_{\mathrm{LS}}$ are available for semiflexible chains.[10] In practice, the expression for rod-like chains (i.e. $\hat{a}/L > 1$) may be used as a first approximation for any $\hat{a}/L$, since $[J_{\mathrm{Vv}}(\delta) R_{\mathrm{G}}^2]_{\mathrm{LS}} \approx (R_{\mathrm{G}}^2)_{\mathrm{LS}}$ and $[J_{\mathrm{Hv}}(\delta) R_{\mathrm{G}}^2]_{\mathrm{LS}} \propto (\delta^2 R_{\mathrm{G}}^2)_{\mathrm{LS}} \approx 0$ as $\hat{a}/L$ becomes small and δ tends to zero for flexible chains;[10] see section 4, "Examples".

2.4 Scattering at Arbitrary Angle and Infinite Dilution

2.4.1 Isotropic Solute in the Rayleigh–Gans–Debye Regime

The angular dependence of the scattering over a wide angular range provides additional information on solute structure and dispersity, at least in principle. In practice, the effects of these two attributes may frustrate analysis, e.g. even in the preceding case for small scattering angle, the dependence of $(R_{\mathrm{G}}^2)_{\mathrm{LS}}$ on average molecular weights depends on the solute structure, see Table 1. For an optically isotropic solute (averaged over all orientations) in the RGD approximation,[1,10,18] Equations (34) and (35) apply

$$P_{\mathrm{Vv}}(\vartheta, 0) = \frac{[\mathbf{R}_{\mathrm{Vv}}(\vartheta, c)/K'c]^0}{M_{\mathrm{LS}} \psi^2_{\mathrm{solute}}} \tag{34}$$

$$P_{\mathrm{Vv}}(\vartheta, 0) = \sum_{\mu} w_\mu M_\mu^{-1} \quad \sum\sum_{ij} \psi_i m_i \psi_j m_j \times \langle \sin(q|r_{ij}|)/q|r_{ij}| \rangle_{\mu} \quad M_{\mathrm{LS}} \psi^2_{\mathrm{solute}} \tag{35}$$

where each sum runs over the M/m scattering elements on a component, and the second form is written in the RGD approximation. Expansion of the factor in $\langle \cdots \rangle$ brackets yields the relation in terms of $(R_{\mathrm{G}}^2)_{\mathrm{LS}}$ given above. Equations (36) and (37) apply to optically identical scattering elements with molar mass m,

$$P_{\mathrm{Vv}}(\vartheta, 0) = \frac{\sum_{\mu} w_\mu M_\mu [P_{\mathrm{Vv}}(\vartheta, 0)]_\mu}{M_{\mathrm{w}}} \tag{36}$$

$$[P_{\mathrm{Vv}}(\vartheta, 0)]_\mu = \left(\frac{m}{M}\right)_\mu^2 \sum\sum_{ij} \frac{\langle \sin(q|r_{ij}|)}{q|r_{ij}|\rangle_\mu} \tag{37}$$

where as above, the ensemble may include chains with identical M_μ but different $[P_{\mathrm{Vv}}(\vartheta, 0)]_\mu$, with w_μ the weight fraction of each distinct component.

Expressions for $P_{\mathrm{Vv}}(\vartheta, 0)$ for a number of widely used models in the RGD approximation are given in Table 2, and a selection are illustrated in Figure 3. The exponential form $P_{\mathrm{Vv}}(\vartheta, 0) = \exp(-R_{\mathrm{G}}^2 q^2/3)$ is included for comparison, as this relation is sometimes used as

Figure 3 Examples of $P_{Vv}(\vartheta, 0)^{-1}$ versus $q^2R_G^2$ for monodisperse model structures (see Table 1). (a) Various-models: Rod-like chains (R), random-flight linear chains (C), disks (D), spheres (S), shells (Sh) and the exponential function $\exp(-q^2R_G^2/3)$ (E), included for comparison; (b) the persistent or worm-like chain, for the indicated values of the ratio of the persistence length $\hat{a}$ to the contour length L.

a convenient approximation; inspection shows that it is not usually a good approximation unless $R_G^2q^2$ is small, providing the best fit for spheres among the examples in Figure 3. Given the availability of computational equipment, it is usually not necessary to resort to tabulated numerical values of $P_{Vv}(\vartheta, 0)$ for scatterers in the RGD approximation; an extensive compilation of formulae for $P_{Vv}(\vartheta, 0)$ for a variety of macromolecular and particle shapes to supplement the entries in Table 2 may be found in Kerker (p. 482).[21] In most cases, $P_{Vv}(\vartheta, 0)$ may be expressed in terms of q in the RGD approximation, but with some structures, $P_{Vv}(\vartheta, 0)$ depends explicitly on ϑ, as well as on q, e.g. for a rod-like chain (see Table 2).

In some models, the summations in $P_{Vv}(\vartheta, 0)$ may be completed in terms of standard molecular-weight averages (M_n, etc.) without specification of a particular expression for the distribution w_μ. For example, for random-flight linear chains (e.g. at the Flory θ temperature), using $P_{Vv}(\vartheta, 0)$ in Table 2,[1,42] Equation (38)

$$P_{Vv}(\vartheta, 0) = \frac{2M_n}{M_w u_n^2} \quad u_n - 1 + \sum_\mu w_\mu \left(\frac{M_n}{M_\mu} \times \exp\left(-u_n \frac{M_\mu}{M_n} \right) \right\} \tag{38}$$

where $u_n = (R_G^2/M)M_nq^2$, with R_G^2/M a constant for this model. Further analysis requires an expression for w_μ, and this would be the normal situation with most forms for $P_{Vv}(\vartheta, 0)$. For example, in this case, using the Schulz–Zimm (two-parameter exponential) distribution function,[1,31,42] the remaining sum is equal to $(1 + u_n/h)^{-h}$, where $h^{-1} = (M_w/M_n) - 1$. For a most-probable distribution of molecular weight ($h = 1$), this reduces the expression to a simple form linear in q^2, Equation (39):[1,31,42]

$$P_{Vv}(\vartheta, 0)^{-1} = 1 + \frac{(R_G^2)_{LS}q^2}{3} \tag{39}$$

exactly, with $(R_G^2)_{LS} \propto M_z$ for this model for a linear polymer.[42,50] The same result obtains for a randomly branched flexible chain polymer.[12] An expression for $P_{Vv}(\vartheta, 0)$ for rod-like chains with the same distribution of molecular weight is available in the form of a series to be summed over $h - 1$ terms.[10] Examples of $P_{Vv}(\vartheta, 0)^{-1}$ computed for the random-flight linear chain and the sphere models using the Schulz–Zimm distribution function are shown in Figure 4.

The expression for $P_{Vv}(\vartheta, 0)$ given in Table 2 for linear flexible coil chains assumes random-flight chain statistics, and therefore is not strictly applicable to polymer chains in so-called "good solvents" (i.e. solvents for which $A_2 \gg 0$), for which excluded volume effects introduce a nonlinear dependence of $|r_{ij}|$ on the separation of scattering elements i and j, resulting in a dependence of R_G^2/L on L (see Yamakawa,[20] p. 302).[51] In practice, the expression given in Table 2 may usually be used in good solvents for the range of $(R_G^2)_{LS}q^2$ of usual interest, provided that the observed $(R_G^2)_{LS}$ is used, as opposed to the value of $(R_G^2)_{LS} = \hat{a}M_z/3$ obtaining under Flory θ conditions ($A_2 = 0$) called for by the model. Treatments attempting to include excluded volume effects by calculation of $P_{Vv}(\vartheta, 0)$ using a model for which $|r_{ij}| = |i - j|^{1+\beta}$, with $0 \leq \beta \leq 1$, have been developed as an alternative.[18,52] Similarly, although $[P_{Vv}(\vartheta, 0)]_{BR}$ has been computed for a variety of branch chain configurations,[12,53,54] the expression $[P_{Vv}(\vartheta, 0)]_{LIN}$ for linear flexible chains provides a first approximation to $[P_{Vv}(\vartheta, 0)]_{BR}$, provided $(R_G^2)_{BR}$ observed for the branched chain is used in place of $(R_G^2)_{LIN}$ appearing in $[P_{Vv}(\vartheta, 0)]_{LIN}$. Examples

Table 2 Intramolecular structure factor for several models[a] (RGD approximation)

Model	R_G^2 [b]		$P_{Vv}(\vartheta, 0)$
Random-flight linear coil	$\hat{a}L/3$	$u = \hat{a}Lq^2/3$	$p_c(u) = (2/u^2)[u - 1 + \exp(-u)]$
Persistent (worm-like) linear chain[c]	$(\hat{a}L/3)S(\hat{a}/L)$	$v = u\hat{a}/L$	$\exp(v) \quad_{i=0}(-v/i!)^{-1}p_c[(v+i)L/\hat{a}]$
Disk "infinitely thin"[d]	$R^2/2$	$y = Rq$	$(2/y^2)[1 - J_1(2y)/y]$
Sphere	$3R^2/5$	$y = Rq$	$(9/y^6)[\sin(y) - y\cos(y)]^2$
Shell "infinitely thin"	R	$y = Rq$	$[\sin(y)/y]^2$
Rod "infinitely thin"[e]	$L^2/12$	$x = Lq$	$p_1(x) = (2/x^2)[xSi(x) - 1 + \cos(x)]$

[a] With one exception, the original citations for the entries for $P_{Vv}(\vartheta, 0)$, along with expressions for a number of additional models may be found in Kerker[21] p. 482. All functions are for full orientational averaging.
[b] $\hat{a}$ is the persistence length; $L = M/M_L$ is the chain contour length (mass per unit length M_L), R is the radius for a disk or shell.
[c] $S(Z) = 1 - 3Z + 6Z^2 - 6Z^3[1 - \exp(-Z^{-1})] \approx (1 + 4Z)^{-1}$, the expression for $P_{Vv}(\vartheta, 0)$ is limited to $\hat{a}/L < 0.1$; a more complete representation may be found in Peterlin.[52]
[d] $J_1(\ldots)$ is the Bessel function of first order and kind.
[e] $Si(x) = \int_0^x ds\{\sin(s)/s\}$ is the sine integral.
For rods with optically anisotropic elements,[10,18,41]

$$\left(1 + \frac{4\delta^2}{5} \quad P_{Vv}(\vartheta, 0) = p_1(x) + \delta^2\left\{\left(\frac{4}{5} \quad p_3(x) - (2 - \delta^{-1})m_1(x) + \left(\frac{9}{8} \quad m_2(x) + m_3(x)\right\}\right.\right.$$

$$P_{Hv}(\vartheta, 0) = p_3(x) + \left(\frac{5}{8} \quad \sin^2\left(\frac{\vartheta}{2} \quad m_2(x)\right.\right.$$

$$p_2(x) = \left(\frac{6}{x^3} \quad [x - \sin(x)]\right.$$

$$p_3(x) = \left(\frac{10}{x^5} \quad [x^3 + 3x\cos(x) - 3\sin(x)]\right.$$

$$m_1 = p_1 - p_2$$

$$m_2 = 3p_1 - p_2 - 2p_3$$

$$m_3 = p_3 - p_2$$

of this are shown in Figure 5 for a range of comb-shaped branched chains with different fractions φ of monomers in the backbone and different numbers of branches f per molecule (e.g. φ is zero and unity for linear and star-shaped structures, respectively[53]); substantial deviations are noted between the approximation and the expected behavior for $(R_G^2)_{BR}q^2 > 3$. It may be noted that the ratio $g = (R_G^2)_{BR}/(R_G^2)_{LIN}$ of the R_G^2 for branched and linear chains of the same M is frequently used in discussions of branched chains, but that is a sufficient descriptor only for self-similar structures, such as star-shaped branched chains. For example, comb-shaped branched chains with different φ and f may have the same g, as exemplified by Equation (40)

$$g \approx \varphi + \frac{(1 - \varphi)^{7/3}(3f - 2)}{f^2} \tag{40}$$

which provides a useful approximation for this model.[53] A similar form applies for randomly branched polymers,[55] with $g_w \approx \varphi_w$, where φ_w is M_w for the longest linear chain in the branched structure divided by the total molecular weight, and $g_w = \left(\quad g_\mu w_\mu M_\mu\right)/M_w$. See further discussion in section 4.

In the limit of very large $(R_G^2)_{LS}q^2$, for thread-like chains in the RGD approximation[10,18,54], Equation (41) applies for a solute with $(R_G^2)_\mu = rM_\mu^\varepsilon$ (e.g. see Table 1),

$$\lim_{(R_G^2)_{LS}q^2 \gg 1}[P_{Vv}(\vartheta, 0)]_\mu^{-1} \approx s_\mu(r_\mu q^2)^{1/\varepsilon} + i_\mu + O(q^{-2}) \tag{41}$$

where i_μ and s_μ are numbers that depend on the solute structure. Thus, for a rod-like solute ($\varepsilon = 2$ and $r = (L/M)^2/12$, with L the chain contour length,[10,18,56] Equations 42 and 43)

$$\lim_{(R_G^2)_{LS}q^2 \gg 1}[P_{Vv}(\vartheta, 0)]_\mu^{-1} \approx \left(\frac{L_\mu}{\pi} \quad q + \left(\frac{2}{\pi^2} \quad + \cdots\right.\right. \tag{42}$$

$$\lim_{(R_G^2)_{LS}q^2 \gg 1} P_{Vv}(\vartheta, 0)^{-1} \approx \left(\frac{L}{\pi M} \quad M_w q + \cdots\right. \tag{43}$$

showing that data on $\mathbf{R}_{Vv}(\vartheta, 0)$ in this limit will provide the length per unit mass, but not the molecular weight; this situation may be realized with certain large rod-like structures.[56] For linear or branched flexible chain polymers ($\varepsilon = 1$ and $r = g\hat{a}L/3M$, with g the ratio of R_G^2 for branched and linear chains with the same M,[10,18,54] Equations 44 and 45)

Figure 4 Examples of $P_{Vv}(\vartheta, 0)^{-1}$ versus $q^2(R_G^2)_{LS}$ for model structures with a weight distribution given by the two-parameter Zimm–Schulz distribution function, with $h = 1/[(M_w/M_n) - 1]$ as per the discussion in the text, for random-flight linear chains (a) and spheres (b), for the indicated values of h, with h decreasing from top to bottom in each set of curves (the uppermost curve for the monodisperse case is bold in each set). The dashed line in (b) is the initial tangent.

$$\lim_{(R_G^2)_{LS}q^2 \gg 1} P_{Vv}(\vartheta, 0)^{-1} \approx \frac{rM_n q^2}{2} + \left(\frac{M_w}{M_n} \quad C + \cdots \right) \tag{44}$$

$$\approx \left(\frac{M_n}{M_z} \quad (R_G^2)_{LS}\frac{q^2}{2} + \left(\frac{M_w}{M_n} \quad C + \cdots \right) \tag{45}$$

where C is 1/2 for linear chains and dependent on chain structure for branched chains. Consequently, in principle, investigation of the limiting behavior at large and small q can provide values for M_n, M_w and M_z for linear flexible chain polymers (or for branched flexible chains for which C is known). In practice, the limiting behavior at large q is seldom observed in light-scattering experiments with flexible chain macromolecules, but it is possible to observe such behavior with low-angle X-ray or neutron scattering – it may, however, be difficult to observe the limiting behavior for large and small q in the same experimental arrangement. Moreover, short-scale chain features not included in the models used to compute $P_{Vv}(\vartheta, 0)$ will introduce behavior not included in these asymptotic expressions for large $(R_G^2)_{LS}q^2$. A related behavior obtains with spheres, in which the value of $P_{Vv}(\vartheta, 0)$ for successive maxima at large qR decay as $(qR)^{-4}$ in the so-called Porod regime (see Kerker,[21] p. 471; Guinier and Fournet,[24] p. 17).[57,58]

Figure 5 Examples of $[P_{Vv}(\vartheta, 0)]_{BR}$ versus $q^2R_G^2$ for comb-shaped branched chain polymers divided by $[P_{Vv}(\vartheta, 0)]_{LIN}$ for linear chains with the same R_G^2 (not the same molecular weight). The number of branches is indicated, along with the fraction φ of mass in the backbone of the branched chain. (From Casassa and Berry.[53])

For a solute monodisperse in molecular weight, but comprising two types of scattering elements,[10,36,37] Equations (46) and (47) apply

$$P_{Vv}(\vartheta, 0) = x[P_{Vv}(\vartheta, 0)]_A + (1 - x)[P_{Vv}(\vartheta, 0)]_B + x(1 - x)[Q_{Vv}(\vartheta, 0)]_{AB} \tag{46}$$

$$[Q_{Vv}(\vartheta, 0)]_{AB} = 2[P_{Vv}(\vartheta, 0)]_{AB} - \{[P_{Vv}(\vartheta, 0)]_A + [P_{Vv}(\vartheta, 0)]_B\} \tag{47}$$

where $x = w_A\psi_A/\psi_{solute}$ as above, and $\psi_{solute} \neq 0$. Here, $[P_{Vv}(\vartheta, 0)]_A$ and $[P_{Vv}(\vartheta, 0)]_B$ are calculated by the

expression given above, and $[P_{Vv}(\vartheta, 0)]_{AB}$ by a variation of this expression with one sum each over scattering elements of type A and B. The expressions for $P_{Vv}(\vartheta, 0)$ in Table 2 apply for $[P_{Vv}(\vartheta, 0)]_A$ and $[P_{Vv}(\vartheta, 0)]_B$, but $[P_{Vv}(\vartheta, 0)]_{AB}$ must be computed for each case. Expansion of $[Q_{Vv}(\vartheta, 0)]_{AB}$ gives the leading term $\Delta_{AB}^2 q^2/3$, with Δ_{AB}^2 as defined above, i.e. $[Q_{Vv}(0, 0)]_{AB} = 0$. Examples are available for random-flight linear chains.[36] Inspection shows that the initial tangent $\partial[P_{Vv}(\vartheta, 0)]^{-1}/\partial q^2$ may be negative, zero, or positive, reflecting the possibility mentioned above that $(R_G^2)_{LS}$ may be positive, zero, or negative, respectively, for such a solute. For a sphere with radius R_A and scattering elements of type A coated by a shell with outer radius $R_B > R_A$ and scattering elements of type B (Kerker,[21] p. 419) (Equation 48)

$$P_{Vv}(\vartheta, 0) = \left(x[P_{Vv}(\vartheta, 0)]_A^{1/2} + (1-x) \times \frac{R_B^3[P_{Vv}(\vartheta, 0)]_B^{1/2} - R_A^3[P_{Vv}(\vartheta, 0)]_A^{1/2}}{R_B^3 - R_A^3} \right)^2 \quad (48)$$

where the expressions for $[P_{Vv}(\vartheta, 0)]_B$ and $[P_{Vv}(\vartheta, 0)]_A$ are the functions for spheres with radii R_B and R_A, respectively (given in Table 2). This expression reduces to $P_{Vv}(\vartheta, 0)$ for a shell of thickness $\Delta = R_B - R_A$ filled with the solvent for $x = 0$, or to $P_{Vv}(\vartheta, 0)$ for a sphere of radius R_A if $x = 1$. In using this relation, it must be remembered that $w_A \propto \rho_A R_A^3$ and $w_B = 1 - w_A \propto \rho_B(R_B^3 - R_A^3)$. If $\psi_{solute} = 0$, then $[\mathbf{R}_{Vv}(0, c)/Kc]^0 = 0$, but $[\mathbf{R}_{Vv}(\vartheta, c)/Kc]^0$ for $\vartheta > 0$ may be computed using Equation (48) with x and $1 - x$ replaced by $w_A\psi_A$ and $w_B\psi_B$, respectively. The result will exhibit a series of maxima for $\vartheta > 0$, with a superficial similarity to $\mathbf{R}_{Vv}(\vartheta, c)$ observed with charged spheres, arising from interactions among the scatterers, see section 4.

2.4.2 *Isotropic Solute Beyond the Rayleigh–Gans–Debye Regime*

Although the accuracy of the RGD approximation varies with ϑ and $\tilde{n}$, deviations from the Mie theory are usually small if $\alpha|\tilde{n} - 1| < 0.25$ (but this depends on ϑ and both α and $\tilde{n}$ individually in detail) (Kerker,[21] p. 427; van de Hulst,[22] p. 131). With the RGD approximation, $P_{Hh}(\vartheta, 0) = P_{Vv}(\vartheta, 0)\cos^2(\vartheta)$, but this relation does not usually hold if the phase shift is not small. The Mie theory provides expressions for $P_{Vv}(\vartheta, 0)$, $P_{Hh}(\vartheta, 0)$, and $P_{Hv}(\vartheta, 0)$ for optically isotropic nonabsorbing spheres as the square of sums over functions of ϑ and the relevant refractive indices (see Bohren and Huffman,[13] p. 113; Kerker,[21] p. 97; van de Hulst,[22] p. 131).[8] Examples shown in Figure 6 give $P_{Vv}(\vartheta, 0)$ as a function of $q^2(R_G^2)_{LS}$ for a particular value of $\alpha = 2\pi R/\lambda$, over a range of $\tilde{n}$, with

Figure 6 Examples of $\log[P_{Vv}(\vartheta, 0)]$ versus $q^2(R_G^2)_{LS}$ for spheres with size parameter $\alpha = 2\pi R/\lambda = 4$ for the indicated values of the relative refractive index $\tilde{n}$. The angular range is 0 to 180 degrees in all cases except for $\tilde{n} = 2$. The RGD limiting case for very small $\tilde{n} - 1$ is given by the bold dashed curve. The dashed line gives the initial tangent. Values of $(R_G^2)_{LS}/(3R^2/5)$ may be seen for this α in Figure 2.

$\lambda = \lambda_0/n_{\text{medium}}$ (e.g. the α value chosen in the example would correspond to aqueous suspensions of spheres with $R \approx 300\,\text{nm}$, with $\lambda_0 = 633\,\text{nm}$). The extreme dependence on $\tilde{n}$ may be observed, emphasizing the need to know this parameter accurately in this regime, and showing that it would be impossible to analyze the size distribution for an ensemble of spheres with heterogeneity of both $\tilde{n}$ and R. The data in Figure 6 are shown as $\log[P_{\text{Vv}}(\vartheta, 0)]$ versus $q^2(R_{\text{G}}^2)_{\text{LS}}$ to emphasize the correspondence at small q, but the systematic variation of $q^2(R_{\text{G}}^2)_{\text{LS}}$ for the first minimum in $P_{\text{Vv}}(\vartheta, 0)$ with $\tilde{n}$. In this format, the minima in $P_{\text{Vv}}(\vartheta, 0)$ tend to occur near the values of $q^2(R_{\text{G}}^2)_{\text{LS}}$ for the minima in the RGD approximation. Similar behavior may be observed for other values of α, including α large enough to be in the Fraunhofer diffraction limit discussed below.

Numerical methods to compute $P_{\text{Vv}}(\vartheta, 0)$ are available for a number of particle shapes (see Bohren and Huffman,[13] p. 475).[8,59,60] Fortunately, electronic computation at the desktop can facilitate the use of these, although extensive tables of the functions appearing in the Mie theory for the scattering from spherical particles are available (Kerker,[21] p. 78) (the functions reported herein were calculated using a MathCad file, kindly provided by D. C. Prieve, of the Department of Chemical Engineering of Carnegie Mellon University, with the number of terms in the relevant sums terminated at the next integer larger than $\alpha + 4\alpha^{1/3} + 4$ (slightly larger than an expression advocated in the literature (see Bohren and Huffman,[13] p. 477) for accessible α); data in published tables[61–63] are useful to confirm the methods used in such calculations). Comparable expressions are available in the Mie approximation for shells, stratified spheres, and examples with a continuous radially symmetric variation (see Bohren and Huffman,[13] p. 475; Kerker,[21] p. 189)[26,64–66] cylinders and ellipsoids (Kerker,[21] p. 255).[67–69] The application of these for polydisperse systems requires the use of Equation (36) to compute the observable $P_{\text{Vv}}(\vartheta, 0)$, usually by a numerical analysis.

For both $\tilde{n} \gg 1$ and phase shift magnitude $\alpha|\tilde{n} - 1| > 10$, the angular dependence reduces to a regime termed the Fraunhofer diffraction limit (see Bohren and Huffman,[13] p. 482; Kerker,[21] p. 159; van de Hulst,[22] p. 108).[11] In that regime, the angular dependence is independent of $\tilde{n}$, and the same for absorbing or nonabsorbing particles. For example, for a spherical solute, the angular dependence of the scattering (for a monodisperse solute at infinite dilution) is that for Fraunhofer diffraction from a circular aperture, Equation (49)

$$\lim_{R/\lambda \gg 1} P_{\text{Vv}}(\vartheta, 0) = \left\{ \frac{2J_1(\alpha \sin(\vartheta))}{\alpha \sin(\vartheta)} \right\}^2 \tag{49}$$

where $\alpha = 2\pi R/\lambda$, $J_1(\cdots)$ is the Bessel function of the first kind and first order. For a polydisperse spherical solute in this regime, Equation (50)

$$\lim_{R/\lambda \gg 1} \frac{\mathbf{R}_{\text{Vv}}(\vartheta, c)}{c}^{0} \propto \sum_{\mu} n_\mu \alpha_\mu^6 \left\{ \frac{2J_1(\alpha_\mu \sin(\vartheta))}{\alpha_\mu^2 \sin(\vartheta)} \right\}^2 \tag{50}$$

where n_μ is the number fraction of spheres with radius R_μ. As discussed below, the simplicity of this result can be exploited in methods to determine the size distribution from $[\mathbf{R}_{\text{Vv}}(\vartheta, c)/c]_0$. Similar results obtain for other particle shapes. For example, for cylinders with length L_{cyl} and radius R, in the same limit, and with $L_{\text{cyl}} \gg R \gg \lambda$ (van de Hulst,[22] p. 108), Equation (51)

$$\lim_{R/\lambda \gg 1} P_{\text{Vv}}(\vartheta, 0) = \frac{\sin^2(\alpha\vartheta)}{(\alpha\vartheta)^3} \tag{51}$$

Since the patterns of the extrema are similar for these two functions, it would not be possible to differentiate between solutes with these two shapes from the scattering in this limit. Nor can the expression for cylinders with $L_{\text{cyl}}/R \gg 1$ be used to determine the distribution of cylinder lengths.

It has been observed that in the regime for which Mie scattering theory applies for optically isotropic spheres, the angular dependence for small angles may be approximated by the expression for the Fraunhofer regime given above, even if R is not much larger than λ (see Kerker,[21] p. 351);[44] Although the discussion of $(R_{\text{G}}^2)_{\text{LS}}$ in the preceding shows that this cannot be accurate for small angles (and is inaccurate for the RGD regime), it may, nevertheless, be a useful approximation over most of the regime for which the Mie theory is needed, offering a substantial simplification in the analysis of the size distribution in such cases.

If $\alpha \gg 1$, but $\tilde{n} \approx 1$ (e.g. for a particle immersed in a solvent with closely matching refractive index), so that the phase shift $\alpha|\tilde{n} - 1|$ is small, the angular dependence differs considerably from that for Fraunhofer diffraction for larger ϑ, in a regime called anomalous diffraction (see van de Hulst,[22] p. 183)[21] giving what has been characterized as "a set of queer scattering diagrams" (van de Hulst,[22] p. 183). So-called anomalous scattering approximations to the Mie theory have been obtained in this regime for spheres (van de Hulst,[22] p. 172), reported to be accurate for computation of $P_{\text{Vv}}(\vartheta, 0)$ in the regime $\tilde{n} - 1 < 0.1$, $2\alpha|\tilde{n} - 1| < 0.1$, and $\alpha > 1$.[70] Use of the Fraunhofer diffraction approximation would, for example, give an erroneous estimate of the size distribution, see section 4. It is reported that depolarized scattering may result from isotropic spheres in this regime.[71] The preceding discussion has been limited to scattering with polarization of the incident and scattered beams either perpendicular or parallel to the scattering plane, the plane defined by incident and scattered beams. A more general notation is needed to discuss the anisotropic scattering for spheres since $P_{\text{Hv}}(\vartheta, 0)$ as

defined above is zero for isotropic spheres. In a more general description, the scattering plane may contain the incident beam and be at an azimuthal angle φ relative to the polarization of the incident light for vertically polarized light. Thus, $\varphi = \pi/2$ for the scattering plane considered thus far. An alternative nomenclature lets Vv and Hv indicate parallel and crossed polars, respectively, as in the preceding, but supplements the description by adding the azimuthal angle, e.g. $P_{\mathrm{Hv}}(\vartheta, \varphi, c)$, so that $P_{\mathrm{Hv}}(\vartheta, 0)$, $P_{\mathrm{Vv}}(\vartheta, 0)$, and $P_{\mathrm{Hh}}(\vartheta, 0)$ discussed above become $P_{\mathrm{Hv}}(\vartheta, \pi/2, 0)$, $P_{\mathrm{Vv}}(\vartheta, \pi/2, 0)$, and $P_{\mathrm{Vv}}(\vartheta, 0, 0)$, respectively. It has long been known that $P_{\mathrm{Hv}}(\vartheta, \pi/4, 0)$ is not zero for optically anisotropic spheres (see below), with a first maximum in $P_{\mathrm{Hv}}(\vartheta, \pi/4, 0)$ occurring at an angle ϑ that may be used to estimate the size of the sphere, see below.[5] Calculations in the RGD approximation and using the Mie theory reveal that a similar maximum occurs with optically isotropic spheres in the anomalous diffraction regime,[71] in agreement with observations on spheres thought to be optically isotropic.[70]

2.4.3 Anisotropic Solute

With the exception of semiflexible chains with relatively large $\hat{a}/L$, anisotropic scattering may normally be neglected in the excess scattering for polymer solutions (note that many solvents will exhibit anisotropic scattering, which must be accurately determined to study the excess anisotropic scattering due to the solute). The functions $P_{\mathrm{Hv}}(\vartheta, 0)$ and $P_{\mathrm{Vv}}(\vartheta, 0)$ for rod-like chains are given in Table 2, and are discussed in more detail below in an example, along with the anisotropic scattering from particles.

Expressions for $P_{\mathrm{Vv}}(\vartheta, 0)$ and $P_{\mathrm{Hv}}(\vartheta, 0)$ for optically anisotropic rod-like molecules in the RGD regime are given in Table 2, and discussed below in section 4. The functions $P_{\mathrm{Hv}}(\vartheta, \varphi, 0)$ and $P_{\mathrm{Vv}}(\vartheta, \varphi, 0)$ defined above have been computed for optically anisotropic spheres and other particle shapes.[5,26,72] A principal result for anisotropic spheres is that $P_{\mathrm{Hv}}(\vartheta, \pi/4, 0)$ exhibits extrema as a function of qR for monodisperse spheres (see Kerker,[21] p. 674),[5,45,70,73–78] see section 4.

2.5 The Size Distribution from Scattering Data at Infinite Dilution

In the preceding, the characterization of the size distribution is through averages of M and R_{G}^2. Thus, with a model relating R_{G}^2 to M, the different averages in M_{LS} and $(R_{\mathrm{G}}^2)_{\mathrm{LS}}$ can permit an estimate of the breadth of the size distribution. Two principal methods are used to estimate more detailed information on the size distribution: (i) comparison of experimental $P_{\mathrm{Vv}}(\vartheta, 0)$ with that calculated with an assumed distribution of M (or some other equivalent size parameter, such as R for spheres), and (ii) inversion of $P_{\mathrm{Vv}}(\vartheta, 0)$ to obtain the size distribution function. Neither is entirely satisfactory, each with its own set of limitations. In either case, it is necessary to have a model for $P_{\mathrm{Vv}}(\vartheta, 0)$, and to assume that the model applies to all scatterers in the system. Further, as a practical matter, it must be assumed that all components are identical in composition. In practice, data on $\mathbf{R}_{\mathrm{Vv}}(\vartheta, c)/Kc$ are often used to estimate a size distribution, rather than $P_{\mathrm{Vv}}(\vartheta, 0)$, or even $[\mathbf{R}_{\mathrm{Vv}}(\vartheta, c)/Kc]^0$. As discussed in the next section, this practice may introduce distortions into the size estimate unless $2(A_2)_{\mathrm{LS}}M_{\mathrm{w}}c \ll 1$. Multiple scattering is an additional practical issue sometimes encountered, especially in the scattering from dispersions of particles for which $\mathbf{R}_{\mathrm{Vv}}(\vartheta, c)/Kc$ is not extrapolated to infinite dilution. Some schemes have been introduced to account for this effect, especially in the scattering from large spheres,[79–83] but in general it should be avoided by reducing the solute concentration, though this can have a deleterious effect on the estimate of the population of very small scattering components in the presence of large particles.

In the first method, a model is used to compute $P_{\mathrm{Vv}}(\vartheta, 0)$ for comparison with the experimental data, based on an (assumed) solute structure and an assumed two or three parameter molecular-weight distribution function, e.g. one of the several functions given by Berry[42] with parameters M_{w}/M_n, M_z/M_{w}, etc. or alternatively, for spheres, these functions are expressed as a distribution in R with parameters R_{w}/R_n, R_z/R_{w}, etc. Estimates of M_{w} and $(R_{\mathrm{G}}^2)_{\mathrm{LS}}$ may be used to guide estimation of the parameters in the distribution function if these are available; in some cases, for a solute with very large M_{w} it may not be possible to obtain the reliable extrapolation to zero scattering angle needed to estimate these parameters. For example, experimental data on $P_{\mathrm{Vv}}(\vartheta, 0)$ for linear flexible chains or spheres (in the RGD regime) could be compared with Figure 4, calculated using the two-parameter exponential function mentioned above, to estimate the molecular-weight dispersion. Comparison with $P_{\mathrm{Vv}}(\vartheta, 0)$ for semiflexible chains provides an example of the ambiguity in matching experimental and calculated $P_{\mathrm{Vv}}(\vartheta, 0)$ unless a reliable model is available. A similar situation obtains with particles, e.g. deviations from spherical symmetry will result in distortions of the scattering function similar to those caused by a distribution of size in spheres.

There is a long history of attempts to implement a direct inversion of $P_{\mathrm{Vv}}(\vartheta, 0)$ (or $[\mathbf{R}_{\mathrm{Vv}}(\vartheta, c)/c]^0$) for polydisperse scatterers (usually particles with spherical symmetry) to obtain a size distribution of the scattering species, much of it demonstrating the difficulty of obtaining reliable results. Present-day treatments are facilitated by the availability of computational facilities at the desk

top to implement the computations, with almost all applications being to the size distribution of particles owing to the nature and limited accessible span of $P_{Vv}(\vartheta, 0)$ for macromolecules. Two principal methods are used, depending on the size of the particles: numerical inversion of the data via iterative techniques,[84–90] and evaluation of an integral expression based on Fraunhofer diffraction for particles with dimensions much greater than the wavelength, $\tilde{n} \gg 1$.[81,91–101] The numerical inversions required are similar in kind to those applied to estimate size distributions from dynamic light scattering data, which involves a similar inversion relation, with similar limitations. For example, inversion is frequently attempted for the normalized electric-field correlation function $g^{(1)}_{LS}(\tau; \vartheta, c)$ of dynamic light scattering, given by[1,10,17,88,102,103] Equation (52) (see also Chu,[7] p. 243)

$$g^{(1)}_{LS}(\tau; \vartheta) = \frac{\sum_{\mu} w_\mu M_\mu [P_{Vv}(\vartheta, 0)]_\mu \exp[-\tau \gamma_\mu(q)]}{M_w P_{Vv}(\vartheta, 0)} \qquad (52)$$

in the limit of infinite dilution, with $\gamma_\mu(q)$ the relaxation rate of the component μ. The similarity of this to the expression, Equation (53)

$$P_{Vv}(\vartheta, 0) = \frac{\sum_{\mu} w_\mu M_\mu [P_{Vv}(\vartheta, 0)]_\mu}{M_w} \qquad (53)$$

of interest here is evident, with a principal distinction being that the range of τ may be made much larger than the corresponding range in ϑ (or q), to the advantage of accuracy in the inversion. On the other hand, data acquisition is usually more time-consuming in dynamic scattering. In some cases, it is convenient to replace w_μ by the number fraction n_μ of species with molecular weight M_μ, with $w_\mu = n_\mu M_\mu / M_n$, but in either case, implementation of an inversion protocol requires a relation between M_μ and a size parameter appearing in $[P_{Vv}(\vartheta, 0)]_\mu$, e.g. as in Table 1. Furthermore, the inversions are ill-posed for both static and dynamic scattering functions and constraints must be imposed to obtain a stable inversion.

It may be noted that expressions of this kind have been used for many years in the analysis of X-ray scattering data on particles, often with $P_{Vv}(\vartheta, 0) \approx \exp(-R^2_G q^2/3)$, along with a model to express R^2_G in terms of M, e.g. $R^2_G \propto M^{2/3}$ for a spherical particle (Guinier and Fournet,[24] p. 151). The several difficulties that hamper the determination of the molecular-weight (or size) distribution by an inversion of $P_{Vv}(\vartheta, 0)$, include:

1. the ill-posed character of the inversion
2. the need to have a theoretical $P_{Vv}(\vartheta, 0)$
3. noise in the data
4. the physical range of ϑ, and hence the limited accessible q
5. uncertainty in the relative refractive index $\tilde{n} = n_{solute}/n_{medium}$
6. the effects of solute aggregation
7. the effects of multiple scattering.

Various procedures have been investigated to effect the inversion, including versions of the methods used to invert dynamic scattering data, such as the constrained regularization method called CONTIN,[102,103] as well as other methods (see Chu,[7] p. 277).[85–89,98,99,104–108] As discussed above, the RGD approximation is generally valid for a nonabsorbing solute if the phase shift within the molecule or particle is small enough. Although this is generally met for a polymeric solute, a direct inversion of $P_{Vv}(\vartheta, 0)$ is seldom of interest in such cases owing to the limited range of $(R^2_G)_{LS} q^2$ typically accessible for the scattering for a polymeric solute, as well as the limitations due to noise in the experimental data, e.g. see the comments above on the difficulties of obtaining reliable behavior at large q. By contrast, with larger particulate solutes, $P_{Vv}(\vartheta, 0)$ may typically cover a wider range, and perhaps exhibit maxima and minima, for the accessible range of $(R^2_G)_{LS} q^2$. As discussed above, the RGD approximation may be used for a range of particle sizes, but in such cases, the range of $(R^2_G)_{LS} q^2$ may not be large, in which case the inversion may not be accurate, depending on the particle shape. For larger phase shift, M_w must be replaced by M_{LS}, and the Mie theory may be used for spheres to compute the $[P_{Vv}(\vartheta, 0)]_\mu$ needed in the inversion for particles with spherical symmetry, albeit with an increase in the computational time required. Similar treatments are available for other shapes, including spherical shells (Bohren and Huffman,[13] p. 109),[45] spheroids of revolution[46] and rods,[67] but it is not possible to permit both the particle shape and the size distribution to be unknowns in an inversion of the scattering from a polydisperse sample. Inversions in this regime may be reasonably stable and accurate, but usually require an accurate estimate of n_{solute}/n_{medium}, along with the attention of one skilled in the art to avoid erroneous results, see section 4.

The expression for $[\mathbf{R}_{Vv}(\vartheta, c)/c]^0$ given above in the Fraunhofer limit, with $R \gg \lambda$, may be used to obtain an integral equation for the number fraction of spheres with a given radius, eliminating the interactive methods described above. Experimental instruments to acquire data for this purpose differ in their design and in the form of the integral expression used.[43,81,91–95,98–101,109–111] A systematic, consistent analysis of these given by Koo and Hirleman[92] is discussed below in section 4.

2.6 Extrapolation to Infinite Dilution

All of the preceding has presumed that $\mathbf{R}_{\text{iso}}(\vartheta, c)/c$ and $\mathbf{R}_{\text{aniso}}(\vartheta, c)/c$ may be reliably extrapolated to infinite dilution. For dilute solutions, as discussed in section 2.1, $\mathbf{R}_{\text{iso}}(\vartheta, c)/c$ may be expressed in the form of Equation (54)

$$\frac{\mathbf{R}_{\text{iso}}(\vartheta, c)}{KMc} = S_{\text{iso}}(\vartheta, c) = \frac{P_{\text{iso}}(\vartheta, c)}{\{1 + c\Gamma_{\text{iso}}(c)P_{\text{iso}}(\vartheta, c)H_{\text{iso}}(\vartheta, c)\}} \tag{54}$$

where $K = K'\psi^2_{\text{solute}}$, with a similar expression for $\mathbf{R}_{\text{aniso}}(\vartheta, c)/c$. The function $H_{\text{iso}}(\vartheta, c)$, which is usually close to unity, is discussed below, as is the possible dependence of $P_{\text{iso}}(\vartheta, c)$ on c, the latter principally reflecting changes in the mean-square radius of gyration with c.[4] Since $P_{\text{iso}}(\vartheta, c) \ll 1$ for $q^2(R^2_{\text{G}})_{\text{LS}} \gg 1$, one can anticipate that $\mathbf{R}_{\text{iso}}(\vartheta, c)/KMc \approx P_{\text{iso}}(\vartheta, c)$, for any concentration in that limit. The range of $(R^2_{\text{G}})_{\text{LS}}q^2$ required to observe this convergence depends strongly on the solute structure.

For $\vartheta = 0$, $P_{\text{iso}}(0, c) = H_{\text{iso}}(0, c) = 1$, and for dilute solutions, a virial expansion may usually be used to represent $\Gamma_{\text{iso}}(c)$, with the result (see Yamakawa,[20] p. 186)[4,10,31] (Equation 55)

$$\frac{Kc}{\mathbf{R}_{\text{iso}}(0, c)} = M^{-1}_{\text{LS}}\{1 + 2(A_2)_{\text{LS}}M_{\text{LS}}c + 3(A_3)_{\text{LS}}M_{\text{LS}}c^2 + \cdots\} \tag{55}$$

For systems with large A_2, "good solvents", the term in c^2 may introduce appreciable curvature, motivating the use of the relation[4,10] Equation (56)

$$\left(\frac{Kc}{\mathbf{R}_{\text{iso}}(0, c)}\right)^{1/2} = M^{-1/2}_{\text{LS}}\{1 + (A_2)_{\text{LS}}M_{\text{LS}}c + \alpha_3((A_2)_{\text{LS}}M_{\text{LS}}c)^2 + \cdots\} \tag{56}$$

where $\alpha_3 = \{3(A_3)_{\text{LS}}M_{\text{LS}}/((A_2)_{\text{LS}}M_{\text{LS}})^2 - 1\}/2$; α_3 tends to be small for systems with large A_2, making the extrapolation more nearly linear with larger $(A_2)_{\text{LS}}M_{\text{LS}}c$ than with the first form. Possible exceptions to the behavior given by these relations may obtain if the solute is charged and the solvent is of very low ionic strength.[16,32]

Although the behavior for more concentrated solutions is outside the scope of this article, it may be noted that expressions are available for moderately concentrated solutions, both in good solvents, and under Flory θ conditions, for which A_2, but not A_3, is zero. In the latter case, the expression given above terminated at the term in c^2 provides a good fit to the data, whereas with good solvents, power-law expressions in A_2Mc may be used to replace the factor in $\{\cdots\}$ in Equation (55)[4,33]

The expression for $(A_2)_{\text{LS}}$ involves a double summation over components, and need not be elaborated here (however, see the example on association, section 4), except to note that for a polydisperse solute, $(A_2)_{\text{LS}}$ is not equal to the corresponding value $(A_2)_{\Pi}$ obtained by osmotic pressure.[4] Further, it may be noted that for polymer chains, for monodisperse solute, A_2 may be expressed in the form of Equation (57) (Yamakawa,[2] p. 289; Yamakawa,[20] p. 134),[4,10,51]

$$A_2 = (A_2)_{\text{ROD}}F\left(\frac{L}{\hat{a}}, z\right) \tag{57}$$

where $(A_2)_{\text{ROD}} = (\pi N_{\text{A}}L^2/4M^2)d_{\text{thermo}}$ is the second virial coefficient for a rod-like chain with thermodynamic diameter d_{thermo}, $z = (3d_{\text{thermo}}/16\hat{a})(3L/\pi\hat{a})^{1/2}$ is a thermodynamic interaction parameter, and $F(L/\hat{a}, z)$ is a function that depends on chain conformation, with $F(L/\hat{a}, 0) = F(0, z) = 1$. For uncharged solute, d_{thermo} is zero at the Flory θ temperature, and increases to about twice the geometric diameter d_{geo} for uncharged solute in so-called good solvents. In good solvents, $A_2M/[\eta] \approx 1$ for linear flexible chains, with $[\eta]$ the intrinsic viscosity.[51] By comparison, for particles interacting through a hard-core potential, (Yamakawa,[20] p. 181), Equation (58) applies

$$A_2 = \frac{4N_{\text{A}}fV_{\text{particle}}}{M^2} \tag{58}$$

where V_{particle} is the particle volume and f is a parameter that depends on the particle shape, e.g. $f = 1$ for a sphere, and $f = L/4d_{\text{geo}}$ for a rod of diameter $d_{\text{geo}} \ll L$; $A_2M/[\eta] \approx 16/5$ for spheres. The behavior with charged solutes or particles is discussed in section 4.

Similar relations obtain for optically anisotropic polymers, but the coefficients are generally smaller, reflecting the origin of the scattering from fluctuations in the orientation of the scattering elements. Thus, for rod-like chains, (Yamakawa,[20] p. 227)[4,10,112] (Equations 59 and 60)

$$\Gamma_{\text{Vv}}(c) = \{2(A_2)_{\text{LS}}M_{\text{LS}} + \cdots\} + \left(\frac{4\delta^2}{5}\right)\Gamma_{\text{Vh}}(c) \tag{59}$$

$$\Gamma_{\text{Vh}}(c) = \frac{(A_2)_{\text{LS}}M_{\text{LS}}}{4} + \cdots \tag{60}$$

or an eight-fold smaller leading term for depolarized scattering than obtains with polarized scattering.

The possible dependence of $P_{\text{iso}}(\vartheta, c)$ and $H_{\text{iso}}(\vartheta, c)$ on c may complicate the extrapolation of data to infinite dilution, or the interpretation of data at a single concentration. For example, the initial tangent, given by Equations (61) and (62)

$$\frac{\partial[Kc/\mathbf{R}_{\text{iso}}(\vartheta, c)]}{\partial q^2} = M^{-1}_{\text{LS}}\left\{\frac{\partial P_{\text{iso}}(\vartheta, c)^{-1}}{\partial q^2} + c\Gamma_{\text{iso}}(c)\frac{\partial H_{\text{iso}}(\vartheta, c)}{\partial q^2}\right\} \tag{61}$$

$$\frac{\partial[Kc/\mathbf{R}_{\rm iso}(\vartheta, c)]}{\partial q^2} = M_{\rm LS}^{-1}\left\{\frac{\partial P_{\rm iso}(\vartheta, 0)^{-1}}{\partial q^2} + c\Gamma_{\rm iso}(c)\,\frac{\partial W_{\rm iso}(\vartheta, c)}{\partial q^2}\right\} \quad (62)$$

may depend on c (the potential dependence of $P_{\rm iso}(\vartheta, c)$ on c is subsumed in the function $W_{\rm iso}(\vartheta, c)$ in the second form); $\Gamma_{\rm iso}$ may be expressed as a virial expansion in dilute solutions. For the range of $(R_{\rm G}^2)_{\rm LS}q^2$ normally accessible with polymer chains, plots of $KMc/\mathbf{R}_{\rm iso}(\vartheta, c)$ versus q^2 are usually observed to be essentially parallel for dilute solutions over a range of c, suggesting that $\partial W_{\rm iso}(\vartheta, c)/\partial q^2$ is small – exceptions may occur for chains with very large M, and the corresponding larger range of $(R_{\rm G}^2)_{\rm LS}q^2$. Note that with the expression for $H_{\rm iso}(\vartheta, c)$ for spheres given below, plots of $KMc/\mathbf{R}_{\rm iso}(\vartheta, c)$ versus q^2 would not be expected to be parallel, unlike the experience with flexible chain polymers. For convenience, the ratio of the initial tangent for small ϑ to the intercept $Kc/\mathbf{R}_{\rm iso}(0, c)$ at concentration c is denoted $b(c)^2 = [c/\mathbf{R}_{\rm iso}(0, c)]^{-1}\partial[c/\mathbf{R}_{\rm iso}(\vartheta, c)]/\partial q^2$, so that, Equation (63)

$$b(c)^2 = \frac{(1/3)(R_{\rm G}^2)_{\rm LS} + c\Gamma_{\rm iso}(c)\partial W_{\rm iso}(\vartheta, c)/\partial q^2}{1 + c\Gamma_{\rm iso}(c)} \quad (63)$$

Consequently, even if $\partial W_{\rm iso}(\vartheta, c)/\partial q^2$ tends to zero (leading to parallel plots of $KMc/\mathbf{R}_{\rm iso}(\vartheta, c)$ versus q^2 over a range of c), $b(c)^2$ will not equal $(R_{\rm G}^2)_{\rm LS}$ unless $c\Gamma_{\rm iso}(c) \approx 2(A_2)_{\rm LS}M_{\rm LS}c \approx 0$, as at very high dilution, or for a dilute solution with $(A_2)_{\rm LS} = 0$.

For $\vartheta > 0$, the function $H_{\rm iso}(\vartheta, c)$ may introduce an additional dependence on ϑ, and for polymer chains, $P_{\rm iso}(\vartheta, c)$ may vary with c, reflecting principally changes in the mean-square radius of gyration with c.[4,33] The behavior for spherical particles interacting through a hard-core potential provides an example of this behavior. In that case, (Guinier and Fournet,[24] p. 48),[4] Equation (64) holds

$$H_{\rm iso}(\vartheta, c) = \frac{[P_{\rm iso}(\vartheta', c)]^{1/2}}{P_{\rm iso}(\vartheta, c)} \quad (64)$$

where $\sin(\vartheta'/2) = 2\sin(\vartheta/2)$, and $P_{\rm iso}(\vartheta, c) = P_{\rm iso}(\vartheta, 0)$ for this model. Consequently, $P_{\rm iso}(\vartheta, c)H(\vartheta, c) = [P_{\rm iso}(\vartheta', 0)]^{1/2}$, and $\mathbf{R}_{\rm iso}(\vartheta, c)/KMc \approx P_{\rm iso}(\vartheta, 0)$ for large $(R_{\rm G}^2)_{\rm LS}q^2$ as expected.

For flexible chain polymers, the mean-square radius of gyration $(R_{\rm G}^2)_c$ at concentration c tends to its value $\hat{a}L/3$ obtaining under Flory θ conditions with increasing c, even in good solvents for which $(R_{\rm G}^2)_c$ exceeds this value at infinite dilution.[4,33] A first approximation to $P_{\rm iso}(\vartheta, c)$ and $H_{\rm iso}(\vartheta, c)$ for flexible chain polymers in this situation is to use the relation for $P_{\rm iso}(\vartheta, c)$ for a random-flight chain with the observed $(R_{\rm G}^2)_c$ at concentration c (as opposed to the value at infinite dilution), along with the above approximation for $H_{\rm iso}(\vartheta, c)$;[4,113,114] Although this provides a qualitatively useful approximation, it may not be quantitatively correct, and should not be relied on if accuracy is critical; in one alternative, the Flory–Krigbaum pair potential (Flory,[29] p. 519) has been used to estimate $H_{\rm iso}(\vartheta, c)$.[115] The effects of electrostatic interactions among charged spheres are discussed in section 4.

3 EXPERIMENTAL METHODS

3.1 Instrumentation

Discussion of the instrumentation, alignment and calibration methods, and methods of treating data may be found in a number of places[1,10,18,116,117] (see also Chu,[7] p. 155) and only a brief account will be given here. Light scattering photometers with a variety of designs and special purposes are commercially available. These comprise several components, including:

1. the incident light source and its associated optics;
2. the light scattering cell;
3. the detector and its associated optics;
4. the electronic components associated with the detector.

In addition, the experiment could require specialized apparatus in special cases, e.g. filters to remove (most of) any fluorescence emission, means of controlling the temperature, etc.

Several factors are necessary in converting the response $G(\vartheta)$ from the detector to useful parameters in the analysis of static light scattering, including:[1,7,10,18,116,118]

1. the dependence of the scattering volume on angle and solvent;
2. the effects of attenuation of the incident or scattered rays;
3. the polarization state of the incident and scattered rays;
4. the relation of the detected signal to the Rayleigh ratio.

Most light scattering photometers make use of laser light sources, ranging from a few milliwatts to a hundred milliwatts or so in output power. Usually this is a plane-polarized state with the electric vector in the direction vertical to the scattering plane (the plane containing the incident and scattered rays), see below. The plane of polarization may then be rotated by rotation of a half-wave plate placed in the incident beam, providing a convenient tool for optical alignment. The detector optics are designed to control the angular acceptance

of the scattered light and the horizontal and vertical dimensions of the scattering volume; the depth of the scattering volume is controlled by the width of the incident beam. One of a few optical designs is usually employed in the detector optics,[1,7,10,18,116,117] and one of two general arrangements to make use of these relations may be found in practice: (i) the use of a single detector mounted on a goniometer for use over a range of scattering angles, and (ii) the use of a separate detector for each angle. The angular resolution and scattering volume must be known at each scattering volume to permit assessment of the Rayleigh ratio. In some designs this is facilitated by insuring that the scattering volume has a vertical dimension smaller than that of the incident beam,[1,18,117] but other procedures may be adopted. It is usually advisable to place a band-pass filter with a high transmission for the scattered light before the detector to minimize the effects of any fluorescence from the sample or stray light from sources other than the incident beam. Similarly, a band-reject filter may be used to assess the presence of fluorescence. It is also advisable to place a polarizing filter of some kind before the detector, and it is essential to do this if the anisotropic scattering is to be studied. Unfortunately, not all commercially available instruments provide the option of placing filters in the scattered beam.

Specialized instruments for examining the scattering profile in the Fraunhofer diffraction limit (very small scattering angles) have been constructed and are commercially available, e.g. see Weiner[119] and Plantz[120] for a discussion of some of these. The instruments differ principally in the manner of data collection: measurement of the intensity at an angle ϑ (within a small span $\delta\vartheta$), or collection over an appreciable angular range $\Delta\vartheta = \vartheta_{max} - \vartheta_{min}$, over a range of values for ϑ_{max}, see section 4 for further discussion. In some cases, these small angle measurements are augmented by scattering measurements at a larger angle (or angles), sometimes using light from a laser with excitation at more than one wavelength to provide scattering over a range of q.

3.2 Methods

The optical clarification of the scattering sample is of paramount importance in obtaining reliable results in light scattering. The clarification should remove extraneous motes or ''dust'', undissolved polymer, gas bubbles, and any other scattering source not intrinsic to the sample of interest. At the same time, the clarification process should not cause unwanted removal of a portion of the sample. Often, in the final stages of clarification, the number of extraneous motes is very small, giving the appearance of a few widely separated bright spots in the sample when the scattering is viewed at a small scattering angle. In some instruments the scattering volume is made small in a strategy to reduce the number of extraneous particles in the scattering volume to zero or one for the most part, owing to the wide separation of any remaining extraneous motes. Since the scattering will then normally be rather different for these two states, it is possible to discriminate against the scattering from the extraneous matter. A similar strategy is sometimes employed in computer-aided data acquisition, by collecting data over a time interval that is long in comparison with the timescale for normal intensity fluctuations, but shorter than the timescale for fluctuations due to diffusion of the extraneous matter. The stronger than normal scattered intensity due to the motes may then be discriminated against in the data collection.

In some cases, the experimental data encompass a limited range of angles (e.g. two or three), leading to the use of ''dissymmetry methods'' to analyze scattering data in the RGD regime, following a procedure introduced early in the use of light scattering to characterize solute dimensions. Often, one of the scattering angles is taken to be 90°. The dissymmetry $Z(\vartheta_1, \vartheta_2) = G(\vartheta_1)V(\vartheta_2)/G(\vartheta_2)V(\vartheta_1)$, with instrument response $G(\vartheta)$ and scattering volume $V(\vartheta)$ for $\vartheta_1 < \vartheta_2$, may be used to estimate $(R_G^2)_{LS}/\lambda^2$ (with $\lambda = \lambda_0/n_{medium}$) provided a model is available, including the effects of molecular-weight heterogeneity. The dissymmetry method may not be applied beyond the RGD regime, because then $Z(\vartheta_1, \vartheta_2)$ is not generally a single-valued function of $(R_G^2)_{LS}/\lambda^2$.[23] The use of supplementary angles ($\vartheta_2 = \pi - \vartheta_1$) will usually make the scattering volumes equal at the two scattering angles, simplifying the analysis. Note that in general, $[\mathbf{R}_{Vv}(\vartheta_1, c)/c]^0/[\mathbf{R}_{Vv}(\vartheta_2, c)/c]^0 \neq \mathbf{R}_{Vv}(\vartheta_1, c)/\mathbf{R}_{Vv}(\vartheta_2, c)$, requiring extrapolation to infinite dilution to determine $Z(\vartheta_1, \vartheta_2)$. In the original dissymmetry method, ϑ_1 and ϑ_2 were equal to 45° and 135°, respectively, so that $V(\vartheta_1) = V(\vartheta_2)$ in a convenient cell geometry (e.g. cylindrical), and $Z(\vartheta_1, \vartheta_2) = G(\vartheta_1)/G(\vartheta_2)$ (see Kerker,[21] p. 432).[23] The value of $(R_G^2)_{LS}/\lambda^2$ may then be used to estimate for $P_{Vv}(\vartheta_3, 0)$ for the assumed model with the correction needed to deduce $[\mathbf{R}_{Vv}(0, c)/c]^0$ from $[\mathbf{R}_{Vv}(\vartheta_3, c)/c]^0$ determined at some particular angle, e.g. $\vartheta_3 = 90°$ in the original method. In some cases, only two scattering angles are used, one being fairly small, and the other being 90°, with due attention to the ratio $V(\vartheta_2)/V(\vartheta_1)$.[119–122] Tables to assist this treatment are available for a number of models,[125] or the relations needed may be readily calculated as required using a desktop computer. The use of $P_{Vv}(\vartheta, 0)$ for a linear chain to estimate $(R_G^2)_{LS}/\lambda^2$ by the dissymmetry ratio for a chain that is branched may introduce an error in the estimate for $(R_G^2)_{LS}$ if $(R_G^2)_{LS}q^2$ exceeds about 1. For example, the deviations shown in Figure 5 would

lead to increasingly serious overestimation of $(R_G^2)_{LS}$ with increasing $(R_G^2)_{LS}q^2$. An example of this effect may be seen for $Z(45, 135)$ versus $(R_G^2)_{LS}/\lambda^2$ for monodisperse linear chains and regular four-arm star branched molecules for the random-flight model.[123]

Finally, other methods of data treatment may be found in the literature. Examples include Guinier plots of $\ln(\mathbf{R}_{Vv}(\vartheta, c)/Kc)$ versus q^2, based on the approximation $P_{Vv}(\vartheta, 0) = \exp(-(R_G^2)_{LS}q^2/3)$ (Guinier and Fournet,[24] p. 21), Casassa plots of $Kc/\mathbf{R}_{Vv}(\vartheta, c)$ versus q for rod-like scatterers, based on Equations (42) and (43),[18,56] Porod plots of $q^2\mathbf{R}_{Vv}(\vartheta, c)/Kc$ versus q, based on $P_{Vv}(\vartheta, 0)$ for worm-like chains, see below (Yamakawa,[2] p. 122),[18,52,124] and plots of $(Kc/\mathbf{R}_{Vv}(\vartheta, c))^{1/2}$ versus q^2, introduced by the author.[10] These are useful for analysis of data on dilute solutions under special circumstances. Thus, the Guinier plot was devised for use with the scattering from particles polydisperse in size and shape, for which a more detailed treatment was not feasible; as seen in Figure 3, the actual scattering behavior is usually not represented by the exponential function over a range of q (unless $(R_G^2)_{LS}$ is very small); with the exponential function providing a useful approximation to larger $q^2R_G^2$ for spheres than for the other examples in Figure 3. The Casassa plot is only useful for very long rod-like solutes for which the asymptotic behavior for large q may dominate the scattering for all accessible q, in which case the tangent provides length per unit mass. Similarly, the Porod plot is designed to elucidate the behavior at large q, and may, for example reveal the persistence length of a semiflexible (worm-like) chain if large enough q can be attained; the Porod plot is usually of most interest with the scattering from X-ray or neutron radiation owing to the need to reach large q. The ''square-root'' plot is based on the observation that for a linear monodisperse random-flight linear chain model, for which R_G^2/M is independent of M, Equation (65)

$$P_{iso}(\vartheta, 0)^{-1/2} = 1 + \frac{R_G^2 q^2}{6} + \cdots \tag{65}$$

facilitates evaluation of the initial tangent[125] and hence R_G^2, because in this case the coefficient of q^4 tends to be smaller in this expansion than in the expansion for $P_{iso}(\vartheta, 0)$. Clearly, the use of $P_{Vv}(\vartheta, 0)^{-1/2}$ to facilitate data analysis should be applied only under appropriate conditions, e.g. it would be inappropriate for the polydisperse solute with a most-probable distribution of molecular weight, see below. Similarly, for monodisperse spheres, $P_{iso}(\vartheta, 0)$ is closely approximated by $\exp(-R_G^2q^2/3)$ for $R_G^2q^2 < 2$, with the deviations growing for larger $R_G^2q^2$, see Figures 3 and 6; this fit is less satisfactory for spheres heterogeneous in size, as may be deduced from Figure 4.

4 EXAMPLES

4.1 Static Scattering and Size Separation Chromatography

The application of light scattering and differential refractometry in on-line analysis of the eluent in size exclusion chromatography (SEC) which separates the eluent by size provides a powerful tool for analysis and characterization and has found wide application, e.g. see Lloyd et al.[126] and Barth and Flippen[127]. Examples include SEC and flow field-flow chromatography (FFFC). Since the solute concentration is usually very low in the eluent, it is normally assumed that $c\Gamma_{Vv}(c) \approx 0$ for all elution volumes, or a correction is made based on an estimate for A_2Mc. With optically isotropic homopolymers, the response h_e of the differential refractometer at elution volume V_e permits evaluation of the weight fraction $w_e = h_e/$ h_e for each V_e (excepting possible end-group effects low M). Then, the static (excess) scattering data $[\mathbf{R}_{Vv}(\vartheta, c)]_e$ at each elution volume may be used to compute the molecular weight as $M_e \approx [\mathbf{R}_{Vv}(\vartheta, c)]_e/Kcw_e[P_{Vv}(\vartheta, c)]_e$, given the concentration $c \propto$ h_e and $\partial n/\partial c$. The factor $[P_{Vv}(\vartheta, c)]_e$ may be evaluated using either an experimental estimate for $[P_{Vv}(\vartheta, c)]_e$ from on-line measurements of $[\mathbf{R}_{Vv}(\vartheta, c)]_e$ as a function of ϑ, or as $[P_{Vv}(\vartheta, c)]_e \approx 1$ if ϑ is small enough. In addition, on-line measurements over a range of scattering angles allow determination of $(R_G^2)_e$ as a function of V_e. In some instruments, $[\mathbf{R}_{Vv}(\vartheta, c)]_e$ is measured only at a single angle, e.g. 90°, with the resulting need to estimate $[P_{Vv}(\vartheta, c)]_e$ at that angle being a possible source of inaccuracy. In other instruments, it is possible to measure the scattering at two or three angles, permitting the use of dissymmetry methods to estimate $[P_{Vv}(\vartheta, c)]_e$ based on an assumed functional form, see for example the discussion of dissymmetry methods above. Comparison of $M_w \approx$ w_eM_e calculated from the data on the eluent with M_w determined directly on the unfractionated polymer provides a self-consistency check.

An example of the use of multiangle light scattering with SEC to study the dimensions of poly(di-*n*-hexylsilane), (PDHS), and poly(phenyl-*n*-hexylsilane), (PPHS), is given in Figure 7 (from Berry and Cotts[1] and Cotts[128]). Figure 7(a) gives M_e and $(R_G^2)_e$ resulting from analysis of the multiangle scattering data, and Figure 7(b) gives the response from the differential refractive index detector, normalized to give the same peak response. As expected from the mechanism of SEC, the values of $(R_G^2)_e$ are the same at a given elution volume for the two polymers, but the values of M_e differ. If the elution volume increments are small enough, then $(R_G^2)_e/M_e$ is expected to approximate the value for a monodisperse chain. Analysis of these data permitted assessment of the difference in R_G^2/M for these polymers, revealing the substantially

Figure 7 Example of the use of multiangle light scattering as an SEC detector in the analysis of PDHS, and PPHS. (a) M_w and $(R_G^2)_{LS}$ resulting from analysis of the multiangle scattering data. (b) The response from the differential refractive index, normalized to give the same peak response. (From Berry and Cotts.[1])

Figure 8 Example of the use of multiangle light scattering as an SEC detector in the analysis of randomly branched poly(methyl methacrylate) (PMMA). (a) M_w and $(R_G^2)_{LS}/M_w$ for the eluent for heterodisperse linear (●) and branched polymers (○) resulting from analysis of the multiangle scattering data, with the dashed line and solid curves giving power law and polynomial extrapolations, as discussed in the text. (b) The ratio $[(R_G^2)_{LS}]_{BR}/[(R_G^2)_{LS}]_{LIN}$ from the data in part (a), using the powerlaw (○) and polynomial (●) extrapolations to estimate $[(R_G^2)_{LS}]_{LIN}$. (Adapted from figures in Jackson et al.[131])

larger persistence length for PPHS, owing to the effects of the phenyl substituent.

Another example is provided by the analysis and characterization of branched macromolecules. Certain polymerizations are expected to produce a randomly branched chain structure, in which the number of branch nodes and their placements are randomly distributed among the chains in the ensemble (Flory,[29] p. 347) In such a case, it is not possible to achieve a simultaneous separation by the number m of branch nodes and overall molecular weight M, as each molecule in the ensemble is distinct in this respect. One could conceive of a separation by either p or M, with each separated component then narrow in one feature and polydisperse in the other. Analysis by SEC of such a polymer suggests that although the polymer at each elution volume V_e is polydisperse in both p and M, the distribution in M is much narrower than that in p.[129] Consequently, on-line determination of M_w and $(R_G^2)_{LS}$ of the eluent as functions of V_e offers the possibility that an average g_e may be estimated for an ensemble that approximates monodispersity in M, with a random distribution in p, with $g_e = (R_G^2)_{LS}/[(R_G^2)_{LS}]_{LIN}$, where $[(R_G^2)_{LS}]_{LIN}$ is for a linear polymer with same molecular weight as the branched chain. In this approximation, theoretical expressions[130] for g for a polymer monodisperse in M, with a random distribution in p, would be used to estimate p; the formula, involving summations, is readily calculated with a desk-top computer. An example of data of this type is given in Figure 8 for samples of linear and branched PMMAs.[131] According to the preceding, these data may be used to estimate g_e and hence the branching frequency, as a function of molecular weight, provided a reliable estimate for $[(R_G^2)_{LS}]_{LIN}$ is available. As demonstrated in Figure 8, the latter may not be readily available at the higher molecular weights encountered with branched chains. For the data in Figure 8, the dependence of $[(R_G^2)_{LS}/M_w]_{LIN}$ on M_w is stronger than anticipated for the larger V_e,

perhaps reflecting the effects of increased molecular weight dispersity with increasing V_e with the column set utilized. Two extrapolations have been presented and used to estimate g_e, with the true value likely to be somewhere between these estimates.

The size distributions in vesicle preparations similar to those described in the next section have been examined using FFFC.[132] Although a procedure involving simultaneous determination of the scattering and the concentration of the eluent could have been followed, only an (excess) instrument response $G(\vartheta, c)$ proportional to $\mathbf{R}_{Vv}(\vartheta, c)$ was determined as a function of elution volume. Owing to the low concentrations used, such that $2A_2Mc \ll 1$, it was assumed that $c\Gamma_{Vv}(c) \approx 0$ in calculations of the number fraction distribution n_μ. Then, since $[\mathbf{R}_{Vv}(\vartheta, c)]_\mu = KM_\mu^2 P_\mu(\vartheta, 0)\nu_\mu N_A$ for each fraction in this approximation, with ν_μ the number concentration, the number fraction was computed from Equation (66)

$$n_\mu = \frac{G_\mu(\vartheta, c)/M_\mu^2 P_\mu(\vartheta, 0)}{\sum G_\mu(\vartheta, c)/M_\mu^2 P_\mu(\vartheta, 0)} \tag{66}$$

In the analysis, $P_\mu(\vartheta, 0)$ was fitted to the expression for a hollow shell (the RGD approximation being adequate), to give the outer radius R_μ for each eluent fraction, on the assumption that the shell thickness Δ_{sh} was invariant with R_μ, and could be evaluated for the unfractionated polymer, as described in the next section. The expression given above was then used to compute M_μ, using R_μ, Δ_{sh}, and the solute specific volume v_2, to permit evaluation of n_μ for each R_μ. As anticipated from the mechanism for FFFC, R_μ increased linearly with elution volume, except for early elution times, for which the weak scattering may have introduced error in the evaluation of R_μ.

4.2 Light Scattering from Vesicles and Stratified Spheres

Many unilamellar vesicles comprise a single closed shell bilayer.[133] They may be prepared with a spherical shape, and that shape may be further stabilized by a slight imbalance in the compositions of the vesicle interior and exterior, to create a (small) positive osmotic pressure on the interior. Such vesicles provide an example of a shell-like structure, with a shell thickness Δ_{sh} generally much smaller than the outer radius R of the vesicle. The thickness Δ_{planar} of an analogous planar bilayer may be computed as $\Delta_{planar} = 2V_{lipid}/A_{lipid}$, where V_{lipid} and A_{lipid} are the volume and cross-sectional area of the molecules in the bilayer, respectively. It is expected that $\Delta_{sh} \approx \Delta_{planar}$ with increasing R. For a shell, Δ_{sh} may be calculated from the ratio of its volume v_2M/N_A to its surface area $4\pi R^2$, where v_2 is the specific volume of the shell, Equation (67):

$$\frac{v_2M}{N_A} = 4\pi R^2 \Delta_{sh}\left\{1 - \left(\frac{\Delta_{sh}}{R} \quad + \frac{(\Delta_{sh}/R)^2}{3}\right\}\right. \tag{67}$$

Consequently, the ratio of v_2M to R_G^2 may be used to approximate Δ_{sh} for spherical, monodisperse vesicles. The relation $P_{Vv}(\vartheta, 0)$ given above for a shell may be used to compute R_G^2 from Equations (68) and (69)

$$R_G^2 = R^2\left(\frac{3}{5}\frac{1-(1-(\Delta_{sh}/R)^5)}{1-(1-(\Delta_{sh}/R)^3)}\right. \tag{68}$$

$$R = \frac{(R_G^2)^{1/2}}{\{1 + (1/2)\beta + (1/20)\beta^2 + \cdots\}} \tag{69}$$

where $\beta = v_2M/4\pi N_A(R_G^2)^{1/2}$. Equation (70) follows

$$\Delta_{sh} = \frac{v_2M}{4\pi N_A R_G^2}\{1 + \left(\frac{1}{3} \quad \beta^2 + 0.06\beta^3 + \cdots\}^{-1}\right. \tag{70}$$

and inspection shows that $\Delta_{sh} \approx v_2M/4\pi N_A R_G^2$ and $R \approx (R_G^2)^{1/2}$ to a good approximation for $\beta < 1$, with correction factors readily calculated using experimental data for β. Light scattering data on unilamellar vesicles of phosphatidylcholine prepared over a range of size were analyzed to obtain R and Δ_{sh}, after extrapolation to infinite dilution, with results which gave Δ_{sh}, a weakly decreasing function of increasing R, tending to Δ_{planar} ($\Delta_{sh} \approx 3.5$ nm and $R \approx 34$–40 nm for the several samples examined).[134,135]

Size distributions for vesicles with characteristics similar to those discussed above have been reported from inversion of $P_{Vv}(\vartheta, c)$, using a nonnegative least squares fit over a predetermined selection of radii, using $P_{Vv}(\vartheta, c)$ for a vesicle, and the assumption that $c\Gamma_{Vv}(c) \approx 0$ in the analysis.[136] The authors report no significant difference between the use of the RGD approximation and the Mie theory for hollow vesicles, owing to the small radius (≈50 nm), and although the distribution functions obtained were reproducible, they did differ significantly from those obtained by inversion of dynamic light scattering data. The latter gave a broader distribution, especially for larger particle radii. Among possible reasons cited for this discrepancy, it was noted that the experimental time required for dynamic data acquisition was much longer than that for static data (hours compared with minutes), and that interparticle aggregation may have intervened during that longer time to introduce errors in the dynamic data. Another example of an analysis on hollow polystyrene spheres dispersed in water[107] produced the results shown in Figure 9, again under the assumption that $c\Gamma_{Vv}(c) \approx 0$. The spheres had a radius of about 0.23 μm, large enough to require the use of Mie theory in the analysis of the data at the larger q; the difference between the use of Mie theory and the RGD

approximation is shown in Figure 9. The size distribution obtained from dynamic light scattering was shifted to smaller sizes, see Figure 9(b), for reasons not definitively understood.

Block copolymers may form a core-shell micelle in solution, with a resemblance to a vesicle or hollow shell, but with scattering from the core as well as the shell.[137] In these cases, for a system with micelles nearly monodisperse in size and structure, $P_{Vv}(\vartheta, c)$ would be given by Equation (48) for a shell in the RGD regime or an appropriate relation for the Mie regime (Kerker,[21] p. 189), with scattering similar to that for a vesicle, but with a core with a refractive index different from that of the solvent. For example, in this case, since $\Delta^2_{AB} = 0$, for the centrosymmetric micelle (Equation 71)

$$(R^2_G)_{LS} = \left(\frac{3}{5}\right)\left\{(xR^2_A) + (1-x)\frac{[R^5_B - R^5_A]}{[R^3_B - R^3_A]}\right\} \quad (71)$$

Figure 9 Example of the scattering from an aqueous dispersion of heterodisperse hollow polystyrene spheres. (a) Scattering function and fits thereto using the RGD approximation and the Mie theory. (b) Number fraction distribution of particles with a given size deduced from the inversion of the scattering function using the RGD approximation and the Mie theory; an estimate determined from analysis of the dynamic light scattering is included for comparison. (From figures in Strawbridge and Hallett.[107])

with the relation discussed above for a sphere of radius R_A coated by a shell of (outer) radius R_B and thickness $\Delta = R_B - R_A$, and $x = w_A\psi_A/[w_A\psi_A + (1 - w_A)\psi_B]$ Since the refractive increments ψ_A and ψ_B may be either negative, positive or zero, as may $(R^2_G)_{LS}$, which consequently does not bear any simple geometric significance. Owing to symmetry, $(R^2_G)_{LS}$ for a sphere with more complex but spherically symmetric distribution $\psi(r)$ of refractive index increment and density $\rho(r)$ about the center of mass may be expressed by converting the summations used above in the RGD approximation to integrals, Equation (72):[21]

$$(R^2_G)_{LS} = \frac{\int_0^R r^4\psi(r)\rho(r)\,dr}{\int_0^R r^2\psi(r)\rho(r)\,dr} \quad (72)$$

For example, the preceding expression results from separating the integrals into two parts, from 0 to R_A, and R_A to R_B.

4.3 Scattering from Very Large Particles

As noted above, for very large spheres, with both $\tilde{n} \gg 1$ and phase shift magnitude $\alpha|\tilde{n} - 1| > 10$, $P_{Vv}(\vartheta, c)$ reduces to the form for Fraunhofer diffraction from a circular aperture (or opaque disk), with the result that an exact integral expression may be written for the inversion of $P_{Vv}(\vartheta, c)$ to obtain the size distribution in terms of the scattered intensities. Thus, in this treatment, use is sometimes made of the expression,[119,132] Equation (73)

$$L(x_1, x_2) = \int_{x_1}^{x_2} s\left\{\frac{2J_1(s)}{s}\right\}^2 ds$$
$$= J^2_0(x_2) + J^2_1(x_2) - [J^2_0(x_1) + J^2_1(x_1)] \quad (73)$$

In this respect, an apparatus is used with a series of concentric-ring photodiodes, with each photodiode spanning successive angular increments. Thus, the forward scattering intensity is determined over a set of annular rings in this apparatus, rather than as a function of ϑ, with the function $L(\vartheta_1, \vartheta_2)$ representing the fraction of the intensity incident on a particle scattered between angles ϑ_1 and ϑ_2. The function $L(0, \vartheta)$ exhibits a series of plateaus for values of ϑ for which $J_1(\alpha\vartheta)/\alpha\vartheta = 0$, the first three of which are given by $\alpha\vartheta$ equal to 3.83, 7.02 and 10.17, e.g. see Bohren and Huffman,[13] p. 111; van de Hulst,[22] p. 110; Weiner,[119] Swithenbank et al.[138] In practice, the available angular range is adjusted for the set of ring photodiodes with fixed geometry by using a series of lenses of differing focal length f to manipulate the angular range, with $\vartheta \approx r/f$, where r is the radial position of the light on the photodiode. The maximum angle used should be large enough to encompass essentially

all of the scattering, for example to avoid skewing the measurement to the larger components in a polydisperse mixture, a problem called *vignetting* in some of the specialized literature in this area;[138] however, see below for an example of a related problem if the minimum angle is too large. Equation (74) applies to the analysis of a polydisperse sample (with $\sin(\vartheta) \approx \vartheta$),[119,138]

$$L(\vartheta_1, \vartheta_2) \propto \sum_{\mu} n_\mu \alpha_\mu^2 \{J_0^2(\alpha_\mu \vartheta_2) + J_1^2(\alpha_\mu \vartheta_2) - [(J_0^2(\alpha_\mu \vartheta_1) + J_1^2(\alpha_\mu \vartheta_1))]\} \tag{74}$$

where n_μ is the number fraction of spheres with radius R_μ. In practice, the sum over μ is approximated by a small number of discrete ''components'', each of these actually representing an average over components in a ''size class'' determined by the mean radius of the detector ring and the focal length of the lens in use.[119]

As mentioned above, a systematic consistent discussion of measurements in the Fraunhofer diffraction regime may be found in Koo and Hirleman[92] for the representative optics and inversion methods. Instruments collecting the scattered light over a small angular increment at a given ϑ are considered, along with instruments collecting light from some small angle $\vartheta_{\min}$ through angles up to ϑ; both types are used in practice. The forms of the integral expressions used in the inversion depend not only on the optical arrangement, but also on the number of times an integration by parts is used to develop the integral equation used, with consequent change in the way data are processed in the inversion. In the ideal case, the accuracy of the inversion would not depend on these factors, but with real data, containing noise, and limited to a range of ϑ by instrument design, these factors usually will affect the outcome. In addition, the method used to present the scattering medium (either as a dispersion in a fluid, or an aerosol) may affect the results. In this analysis, the expression for $\mathbf{R}_{\mathrm{Vv}}(\vartheta, c)$ in the Fraunhofer limit is recast as an integral, Equation (75):[92]

$$\vartheta^a \mathbf{R}_{\mathrm{Vv}}(\vartheta, c) \propto \int_0^\infty k_{ab}(\alpha, \vartheta) \alpha^b n(\alpha)\, \mathrm{d}\alpha \tag{75}$$

where $\alpha = 2\pi R/\lambda$, $n(\alpha)$ is the (number) fraction of spheres with radius between R and $R + \mathrm{d}R$ (for fixed λ), the factors ϑ^a and α^b account for possible variation of the aperture over which the scattering is collected and the conversion to distributions in terms of particle volume ($b = 2$) or area ($b = 1$), respectively, and $k_{\mathrm{ab}}(\alpha, \vartheta)$ is the appropriate scattering function for the particle. For spheres, (with $\sin(\vartheta) \approx \vartheta$), Equation (76) applies

$$k_{\mathrm{ab}}(\alpha, \vartheta) = \frac{J_1^2(\alpha\vartheta)}{\vartheta^{2-a}\alpha^{b-2}} \tag{76}$$

This expression may then be inverted to obtain $\alpha^b n(\alpha)$ for each α as an integral over ϑ (from 0 to ∞) of a kernel comprising functions of $\alpha\vartheta$ and derivatives of $\vartheta^a \mathbf{R}_{\mathrm{Vv}}(\vartheta, c)$. The result may be cast in several forms, depending on a, b, and whether use is made of integration by parts in obtaining the relation used in the inversion. The required range of ϑ is, of course, nonphysical, but as the kernel involved reduces to essentially zero with increasing ϑ, the effect of the nonphysical upper limit on ϑ is usually nil. The inversion of noise-free scattering data over a span in ϑ typical of commercially available photometers is considered by Koo and Hirleman[92] for five different arrangements and a range of particle sizes (mean diameters of 7–506 μm) over a certain distribution of sizes given by a log-normal function in the particle area. Several statistical measures of the fit of the inversion to the starting size distribution were evaluated in order to arrive at the following principal conclusions in this idealized comparison: (i) the various methods are essentially equivalent over a relatively narrow range of particle size, but differ markedly for either small or large particles, (ii) none of the methods provide a satisfactory representation of the distribution of the smaller particles, and (iii) the methods vary considerably in their performance for distribution of larger particles. These results suggest that whereas the response may be reproducible, and therefore of use as a quality control protocol, the absolute distribution should be accepted with caution.

An example of the comparison of the size distribution deduced for some aerosols using an apparatus of the type described above with $L(\vartheta_1, \vartheta_2)$ determined over a set of angles is shown in Figure 10, including results obtained by inversion of $\mathbf{R}_{\mathrm{Vv}}(\vartheta, c)$, and by fitting $\mathbf{R}_{\mathrm{Vv}}(\vartheta, c)$ with an assumed size distribution.[139] An example of the effect of the choice of the focal length f of the lens used on the analysis is illustrated in Figure 11 for the scattering from polydisperse glass beads with a size distribution (20–170 μm) calibrated by microscopic measurements on a large sample of the beads (National Institute of Standards and Technology (NIST) Standard Reference Material 1004).[138,140] Data were taken in the Fraunhofer regime ($\tilde{n} \approx 1.146$ and phase shift magnitude $\alpha|\tilde{n} - 1| > 40$) with both 100 and 300-mm focal length lenses. Whereas the latter fitted the reported size distribution well, except for the largest size, the data with the smaller focal length lens did not afford a measurement at small enough ϑ to permit a satisfactory assessment of the population of the larger beads.

As mentioned above, the scattering from large particles immersed in a solvent such that $\tilde{n} \approx 1$ may not be in the Fraunhofer regime, but rather may exhibit anomalous diffraction. The assumption that Fraunhofer diffraction

Figure 10 Example of the scattering from a heterodisperse aerosol. (a) Scattering function (solid curve) and fits thereto using the Fraunhofer diffraction approximation and an assumed size distribution function. (b) Weight fraction distribution of particles with a given size deduced from the inversion of the scattering function using the Fraunhofer diffraction approximation (solid curve) and the function used in part (a) (dashed curve). (Adapted from figures from Meyer and Chigier.[139])

applies may lead to serious error in the size distribution determined from the angular profile of the scattered light. An example of this is given in Figure 11, showing data obtained with the 100-mm focal length lens and dispersions in different liquids to provide two values of $\tilde{n}$ close to unity ($\tilde{n} \approx 1.02$ and 1.08).[138,140] The data on $L(\vartheta_1, \vartheta_2)$ show the profound effect of $\tilde{n}$. The expressions for the anomalous scattering regime were used to compute $L(\vartheta_1, \vartheta_2)$ using the size distribution, with the results being a reasonable fit to the data for both values of $\tilde{n}$. Further, the data for $\tilde{n} \approx 1.02$ were inverted under two assumptions: the use of the relations for the Fraunhofer and anomalous scattering regimes. Whereas the latter was in reasonable agreement with the result obtained with data in the Fraunhofer regime ($\tilde{n} \approx 1.146$), the use of the expressions for the Fraunhofer regime gave erroneous results, as expected.

4.4 Intermolecular Association

Intermolecular association is not uncommon in macromolecular solutions or dispersions of particles, especially in aqueous solvent. In general, two forms may be encountered in the extreme: association involving two or more components at equilibrium at any given concentration; and metastable association, in which the components present depend on processing history, but do not change sensibly with concentration in the range of interest for light scattering. Of course, intermediate situations may also occur.

Aside from any criterion imposed by the anticipated nature of the solute, the experimenter may have little reason to suspect association from the dependence of the scattering on concentration in the case of a metastable association. In some cases of metastable association, the molecular weight deduced from extrapolation of $Kc/\mathbf{R}_{Vv}(\vartheta, c)$ to zero q and infinite dilution will depend on temperature or solvent, revealing the association. An example of this sort in which the nature of intermolecular association of a solute with a helical conformation was elucidated by the use of static and dynamic light scattering as a function of temperature is given by Yue et al.[141] In the cited case, the scattering at any given temperature exhibited "normal" behavior and could not have been analyzed to reveal association if taken alone. In a different and somewhat unusual, but not unique, example, it has been reported that $Kc/\mathbf{R}_{Vv}(\vartheta, c)$ is linear in q^2, albeit giving a molecular weight that is much larger than the true value of M_w for the solute.[142] This was observed with a system that formed a gel at a higher solute concentration, suggesting that the observed scattering behavior reflects the anticipated $P_{Vv}(\vartheta, c)$ for a randomly branched polymer.[6] More frequently, with intermolecular association involving flexible chain polymers, $Kc/\mathbf{R}_{Vv}(\vartheta, c)$ exhibits enhanced scattering at small q. This is often taken as evidence for the presence of an aggregated species mixed with solute that is either fully dissociated, or much less aggregated. Although reasonable, it should be realized that such an interpretation is not unique.

A well-defined analysis is possible, at least in principle, for a case with equilibria among otherwise monodisperse monomers, dimers, etc. e.g. the equilibria obtaining among monomers, dimers, and tetramers for hemoglobin in solution.[143,144] Equilibrium association can lead to nonparallel plots of $Kc/\mathbf{R}_{Vv}(\vartheta, c)$ versus q^2 if the species are large enough. In the ideal situation, the ratio of R_G^2 for the aggregates to the unimer would be precisely known, as would be the effect of association on A_2, permitting an assessment of the equilibrium constant for the association for a given model.[144] An illustrative example of the

Figure 11 Example of the scattering from heterodisperse glass particles dispersed in different solvents to span a range of $\tilde{n}$. (a) Scattering function (points and solid curve) obtained using a lens with a 100-mm focal length and solvents to give the indicated $|\tilde{n} - 1|$, and fits thereto using the Mie theory and the known size distribution function (dashed curves). (b) Cumulative weight distribution of particles with a given size deduced by several methods: solid squares, from microscopic measurements (the ''known'' distribution function), as reported by NIST (see text), open squares and open diamonds, from inversion of inversion of the scattering function using the Mie theory for $|\tilde{n} - 1| \approx 0.15$ and two lenses, with focal lengths 300 mm (squares) and 100 mm (diamonds), and circles, for solvents to give $|\tilde{n} - 1| \approx 0.02$ calculated with the assumption of Fraunhofer diffraction (solid circles and dashed line) or anomalous diffraction (open circles and solid line). (Adapted from figures in Brown et al.[140])

effects of association is given in Figure 12. The example was calculated on the assumption that a monodisperse linear flexible coil chain of molecular weight M may undergo end-to-end dimerization to create a linear chain of molecular weight $2M$, with equilibrium constant K_{eq}. Further, it was assumed that $\partial \ln R_G^2 = \partial \ln M = \varepsilon$, and $\partial \ln A_2 = \partial \ln M = \gamma$, with $\varepsilon = 2(2 - \gamma)/3$, following the usual approximation for flexible chain polymers (see Yamakawa,[20] p. 146; Flory,[29], p. 536).[51] Finally, in addition to the expressions for $M_{LS} = M_w$, $(R_G^2)_{LS} = (R_G^2)_z$, and $P_{Vv}(\vartheta, c)$ given above, $(A_2)_{LS}$ was calculated as,[10,18] (Equation 77)

$$(A_2)_{LS} = \frac{\sum_{\mu}\sum_{\nu} w_\mu M_\mu w_\nu M_\nu (A_2)_{\mu\nu}}{M_w} \tag{77}$$

where $(A_2)_{\mu\mu}$ is A_2 for monodisperse component μ, and $(A_2)_{\mu\nu}$ is approximated by $\{(A_2)_{\mu\mu}(A_2)_{\nu\nu}\}^{1/2}$.[10,18] With the use of these relations, Equation (78–82)

$$M_w = M(2 - \zeta) \tag{78}$$

$$(R_G^2)_z = (R_G^2)_M \frac{[\zeta + 2^{1+\varepsilon}(1 - \zeta)]}{(2 - \zeta)} \tag{79}$$

Figure 12 Scattering functions for an illustrative example of a flexible chain polymer undergoing end-to-end dimerization. (a) Dependence on angle, calculated as discussed in the text for a reduced equilibrium constant $K_{eq} = 0.1$ and the indicated values of $(A_2)_M Mc$, with the constant equal to zero or 0.2 for the solid and dashed curves, respectively. (b) Scattering extrapolated to zero angle as a function of $(A_2)_M Mc$, for the indicated values of K_{eq}.

$$P_{Vv}(\vartheta, c) = \left\{ \alpha[P_{Vv}(\vartheta, c)]_M + \frac{2(1-\zeta)[P_{Vv}(\vartheta, c)]_{2M}}{(2-\zeta)} \right\} \tag{80}$$

$$(A_2)_{LS} M_w = \frac{(A_2)_M M\{\zeta + 2^{1+\gamma/2}(1-\zeta)]^2\}}{(2-\zeta)} \tag{81}$$

$$\zeta = \left(\frac{\tilde{K}_{eq}}{2(A_2)_M Mc} \right) \left(\frac{1 + 4(A_2)_M Mc}{\tilde{K}_{eq}} \right)^{1/2} - 1 \tag{82}$$

where ζ is the degree of association, and $P_{Vv}(\vartheta, c)$ is given by the expression in Table 2, with u replaced by $2^{\varepsilon}u$ for $[P_{Vv}(\vartheta, c)]_{2M}$. The calculations were completed for $\varepsilon = 7/6$ ($\gamma = 1/4$), over a range of $(A_2)_M Mc$ and $\tilde{K}_{eq} = (A_2)_M M^2 K_{eq}$. It may be noted that for large $\tilde{K}_{eq}$, the extrapolation to obtain the true molecular weight M at infinite dilution ($\zeta = 0$) may not be possible and the experimenter may erroneously assume that the molecular weight of the polymer at infinite dilution is $2M$. The effect of the association in producing nonparallel $Kc/\mathbf{R}_{Vv}(\vartheta, c)$ versus q^2 for data at different concentration is illustrated in Figure 12.

The situation is usually more complex than the idealized equilibrium association, and analysis of such behavior is sometimes facilitated by an approximate representation with a few "pseudo" components (often two), each of which dominates the scattering over a limited range of q, with M, A_2 and $P_{Vv}(\vartheta, c)$ replaced by their light scattering averages for each pseudocomponent. That is (Equation 83),

$$\mathbf{R}_{Vv}(\vartheta, c) \approx \sum_{\mu} [\mathbf{R}_{Vv}(\vartheta, c)]_{\mu} = K \sum_{\mu} \left(\frac{Mc}{P_{Vv}(\vartheta, c)^{-1} + 2A_2 Mc} \right)_{\mu,c} \tag{83}$$

where the subscript "c" indicates that the parameters M and A_2, and the character of the function $P_{Vv}(\vartheta, c)$ may all depend on c through the dependence of the state of aggregation on c; note that this form does not properly account for the averaging among scattering elements, but it can provide a useful approximation if the components are few and widely separated in size. The analysis of the suspected association by this relation is similar to the determination of the size distribution discussed above in the absence of association, but is made more complex because it involves data over a range of c, with concentration-dependent parameters, and the function $P_{Vv}(\vartheta, c)$ may not be the same, or even known, for all of the aggregates present, and may depend on c. In some of the literature on small-angle X-ray scattering, it has been common to assume that $P_{Vv}(\vartheta, c) \approx \exp[-(R^2_G)_{LS} q^2/3]$ for each pseudocomponent, and frequently to assume that $2A_2 c \ll 1$ in an analysis used to estimate $(M_w)_{\mu} w_{\mu}$ and $[(R^2_G)_{LS}]_{\mu}$ for the assumed pseudocomponents as a function of the overall concentration c (Guinier and Fournet,[24] p. 151). Similar treatments are applied with light scattering, often restricted to small enough q that the expansion of $P_{Vv}(\vartheta, c)$ may be applied. The advent of dynamic light scattering has allowed some improvement in analyses of this type, since a similar expression (Equation 84) for the dynamic scattering can be applied in terms of pseudocomponents (see Equation 52):

$$g^{(1)}(\tau; \vartheta, c) \approx \sum_{\mu} r_{\mu}(\vartheta, c) \exp[-\tau \gamma_{\mu}(\vartheta, c)] \tag{84}$$

where $r_{\mu}(\vartheta, c) = [\mathbf{R}_{Vv}(\vartheta, c)]_{\mu} / \mathbf{R}_{Vv}(\vartheta, c)$. Analysis of $g^{(1)}(\tau; \vartheta, c)$ then provides information on $(M_w)_{\mu} w_{\mu}$ and a hydrodynamic length $[a_{LS,}]_{\mu} = kTq^2/6\pi\eta_s\gamma_{\mu}(\vartheta, c)$ for

each component, and some degree of consistency is expected among the estimates for $(M_w)_\mu w_\mu$ obtained in the two experiments. Further, comparison of $[a_{LS}]_\mu$ and $[(R_G^2)_{LS}]_\mu$ can provide insight into the nature of the component. In some cases, it may be reasonable to estimate $(M_w)_\mu$ for the component with smallest $(M_w)_\mu$ with the assumption that $w_\mu \approx 1$ for that component, i.e. the scattering at small q reflects a small fraction of a large component. An example of a treatment of this kind may be found in Einaga and Berry.[145] In some cases, the depolarized scattering can be particularly useful if the association induces order in the aggregated species.[146,147]

4.5 Scattering with Charged Species

In some cases, the polymeric and colloidal scattering species may bear electric charge. Whereas synthetic polyelectrolytes usually bear either anionic or cationic charge, biological macromolecules are often amphoteric, with a chain bearing both positive and negative charges. Electrostatic interactions among the scatterers may have two effects on macromolecules: (i) they may cause an expansion of the chain dimensions of macromolecules by intramolecular interactions, and (ii) they may alter the scattering through the effects of intermolecular interactions. Only the latter effect is relevant to charged particles. In the extreme, these interactions may lead to interactions with a very long coherence length, making it impossible to apply the relations discussed above.[16] Fortunately, for the purposes of size characterization, the effects of electrostatic interactions on $\mathbf{R}_{Vv}(\vartheta, c)$ and $\mathbf{R}_{Hv}(\vartheta, c)$ may be suppressed or screened by the presence of supporting simple electrolyte in the solution, thereby permitting application of the relations presented above, with one stipulation: the refractive index increment $(\partial n/\partial c)_\Pi$ must be determined for the solution in osmotic equilibrium with the solvent containing the supporting electrolyte.[16,18] Measurement of $(\partial n/\partial c)_\Pi$ can be achieved by equilibrating the solution with the mixed solvent through a membrane of the kind used in measurements of the osmotic pressure. The same procedure must be made with any mixed solvent with components of different refractive index, e.g. a mixed solvent comprising two organic liquids.

The Debye electrostatic length κ^{-1} provides an important measure of the spatial range of electrostatic interactions, with electrostatic interactions being suppressed between charged species that are much further apart than distance κ^{-1}. Here (in the electrostatic unit system most often employed by physical chemists, Equation 85)

$$\kappa = (8\pi N_A L_B I_0)^{1/2} \tag{85}$$

where $I_0 = \quad z_\mu^2 m_\mu/2$ the ionic strength derived from small molecule ions in the solution, m_μ being the molar concentration of species μ with charge z_μ, and $L_B = e^2/\varepsilon kT$ the Bjerrum length, with ε the dielectric constant (relative permittivity) of the solvent and e the charge on an electron. (It should be noted that variations of this expression with a factor $4\pi\varepsilon_0$ multiplying ε appear if SI units are employed, with ε_0 the permittivity of free space). Thus, at 25 °C, $L_B/\text{nm} \approx 57/\varepsilon$ and $\kappa^{-1}/\text{nm} \approx (4.57\pi N_A \quad z_\mu^2 m_\mu/\varepsilon)^{-1/2}$, or $L_B \approx 0.7$ nm and $\kappa^{-1}/\text{nm} \approx 0.42/\quad \tilde{m}_\mu/\text{mol L}^{-1}\ ^{1/2}$ for an aqueous solution of univalent charged simple electrolyte at 25 °C. With polyelectrolyte macromolecules, it is often convenient to adjust the supporting electrolyte composition to a level such that κ^{-1} is comparable to the geometric dimensions of a chain element. In this case, the thermodynamic diameter d_{thermo} appearing, for example in expressions for A_2, will not be dominated by the electrostatic interactions among chains, and the effects of intramolecular electrostatic interactions on the chain dimensions will be largely suppressed.[16,32,51,148] If this is not done, reliable extrapolation of $Kc/\mathbf{R}(0, c)$ to infinite dilution may be impossible if $\kappa^{-1} > (M/cN_A)^{1/3}$; an example of this effect for a rod-like chain is shown in Figure 13(a).[149] A similar effect will obtain with charged particles in solutions, e.g. as is well known, interparticle electrostatic repulsion among spheres can be strong enough to lead to an ordered mesophase with increasing c if the average separation of the spheres is less than κ^{-1}.[150] In addition, for macromolecules, the chain dimensions may expand with increasing κ^{-1} if $\kappa^{-1} > d_{geo}$, where d_{geo} is the geometric diameter of the chain repeat unit; an example of this is shown in Figure 13(b).

It should be realized that an aqueous solution of an organic solute is often close to intermolecular association, and that the addition of salt and consequent suppression of electrostatic interactions may induce association. Thus, with amphoteric proteins, it is often found that association will occur if the pH is adjusted to the isoelectric point, a condition for which appreciable numbers of anionic and cationic sites coexist on the chain.[16] For a pH far from the isoelectric point, the amphoteric macromolecule behaves as either an anionic or a cationic polyelectrolyte and the net charge can help stabilize the solution against association.

The effects of electrostatic interactions between charged spheres dispersed in a medium of low ionic strength can lead to a striking effect on $\mathbf{R}_{iso}(\vartheta, c)/KMc$, resulting from large values of $c\Gamma_{iso}(c)$ from electrostatic repulsion between the spheres. Thus, in this regime, Equation (86)

$$\frac{\mathbf{R}_{iso}(\vartheta, c)}{KMc} = \frac{P_{iso}(\vartheta, c)}{\{1 + c\Gamma_{iso}(c)P_{iso}(\vartheta, c)H_{iso}(\vartheta, c)\}} \approx \{c\Gamma_{iso}(c)H_{iso}(\vartheta, c)\}^{-1} \tag{86}$$

Figure 13 Scattering from a semiflexible polyelectrolyte chain in solvents with low and high ionic strengths (open and solid circles respectively). (a) $10^3\sqrt{Kc}/\mathbf{R}_{Vv}(0, c)$ versus concentration c; the dashed line is to emphasize the extreme nonlinear behavior for the case with a low ionic strength. (b) $10^6 Kc/\mathbf{R}_{Vv}(\vartheta, c)$ versus $\sin^2(\vartheta/2)$. (Adapted from figures in Sullivan and Berry.[149])

where $H_{iso}(\vartheta, c)^{-1}$ is expected to exhibit a maximum associated with the distance of average closest approach of the spheres, e.g. the expression for $H_{iso}(\vartheta, c)$ given above for uncharged spheres. Data on several dilute dispersions of charged polystyrene spheres ($R = 45$ nm) are given in Figure 14.[151] Similar results are reported for solutions of polyelectrolytes and for other charged particles.[148] As mentioned above, these curves bear a qualitative similarity to those obtaining for coated spheres under some conditions with the zero average refractive index increment, but their origin is very different, as is their shape in detail. A first-approximation to $H_{iso}(\vartheta, c)$ might be obtained by using $\sin(\vartheta'/2) \approx (2L_\kappa/R)\sin(\vartheta/2)$ in the expression for hard spheres if $L_\kappa \gg R$, where L_κ is an electrostatic length, expected to be related to κ^{-1}.[148,152] This approximation gives far too sharp a maximum, and values of L_κ to match the position of the maximum that are far larger than κ^{-1}.[151] In addition to the weakness of the ad hoc model, at least a part of this discrepancy may reflect heterogeneity or fluctuation of the charge density, which may broaden the peak.

Figure 14 Dependence of the structure factor on qR for polystyrene spheres ($R = 45$ nm) immersed in deionized water, with the number concentration $\nu = 2.53$, 5.06, 7.59 and 10.12 particles μm^{-3} for the circles with increasing depth of the shading, respectively. (Adapted from figures in Grüner and Lehman.[151])

4.6 Scattering from Optically Anisotropic Solute

Although the (excess) scattering from polymer solutions is usually too small to be of much interest, exceptions can arise for chains with a semiflexible, or rod-like, conformation, and with spheres comprising optically anisotropic scattering elements. It is often assumed that the refractive index tensor of the scattering elements has cylindrical symmetry, with refractive index $n_\parallel$ and $n_\perp$ parallel and perpendicular to the cylinder axis, respectively.[10,49] For this model, the orientationally averaged refractive index is $\tilde{n}_{solute} = (n_\parallel + 2n_\perp)/3$, $\psi_{solute} \approx (\tilde{n}_{solute} - n_{medium})/\rho_{solute}$, and $\gamma_{solute} \approx (n_\parallel - n_\perp)/\rho_{solute}$, with ρ_{solute} the density of the solute (see Equation 9). If $\psi_{solute} \neq 0$, it is convenient to define the optical anisotropy of the scattering element as $\delta_0 = \gamma_{solute}/\psi_{solute}$.

A macromolecular model of interest is that of the persistent, or worm-like chain of contour length L and persistence length $\hat{a}$, with a cylindrical polarizability tensor for the scattering elements, each having an optical anisotropy δ_0. For this model, the mean-squared molecular anisotropy form factor is given by Equation (87),[10,40,41,48]

$$(\delta/\delta_0)^2 = \left(\frac{2}{3Z}\right)\{1 - (3Z)^{-1}[1 - \exp(-3Z)]\} \quad (87)$$

where $Z = L/\hat{a}$; the corresponding expression for R_G^2 is given in Table 2. In the limit where $\hat{a} \ll L$, as for a flexible chain polymer (e.g. vinyl polymers and most

Figure 15 Dependence of $(R_G^2)_{LS}$ and $(\delta/\delta_0)^2_{LS}$ on the ratio of the weight-average contour length to the persistence length for rod-like molecules with a distribution of contour lengths in parts (a) and (b) respectively. (Adapted from figures in Berry.[10])

condensation polymers), $(\delta/\delta_0)^2$ tends to proportionality where $\hat{a}/L = \hat{a}M_L/M$, and M_L is the mass per unit chain contour length. As a consequence $\mathbf{R}_{Hv}(0, c)$ is proportional to the molecular weight of a chain element of length $\hat{a} \ll L$, is much smaller than $\mathbf{R}_{Vv}(0, c)$ for such chains, and may be neglected when considering $\mathbf{R}_{Vv}(0, c)$. In the opposite extreme where $L \ll \hat{a}$, as for a rod-like chain, $\delta \approx \delta_0$, and the anisotropic scattering must be taken into account to determine M_w from $\mathbf{R}_{Vv}(0, c)$. For chains with an overall rod-like character arising from helical structure, δ_0 may be so small that the anisotropic scattering may still be ignored when determining M_w from $\mathbf{R}_{Vv}(0, c)$. Nevertheless, $\mathbf{R}_{Hv}(0, c)$ may be of interest itself to evaluate δ^2 for use in an estimation of the persistence length. An example of a comparison of δ^2 as a function of L used to estimate δ_0^2 and $\hat{a}$ for a rod-like polymer is given in Figure 15.

As mentioned above, $P_{Hv}(\vartheta, \pi/4, 0)$ exhibits extrema as a function of qR for monodisperse spheres, for calculations in the RGD regime[72] and in the anomalous diffraction approximation,[70] the values of qR for these first maxima and following minima may be used to estimate R. In addition, the effects on the scattering pattern of the distortion of the anisotropic sphere, as might occur under a deformation, have been studied, see for example the discussion and literature citations in Samuels.[153]

LIST OF SYMBOLS

$\hat{a}$	Persistence length for semiflexible chains
A_2, A_3	Second virial coefficient third virial coefficient, etc.; see Equation (8)
$b(c)$	Correlation length obtained from the dependence of $\mathbf{R}_{Vv}(\vartheta)$ on ϑ; see Equation (63)
c, c_μ	Solute concentration (wt/vol); concentration of solute component μ
$F_{iso}(\vartheta, c)$	Intermolecular structure factor $\mathbf{R}_{iso}(\vartheta, c)/KcMP_{iso}(\vartheta, c)$; see Equation (4)
$g^{(1)}(\tau; \vartheta, c)$	Normalized electric field autocorrelation function, $g^{(1)}(\tau; \vartheta)$; see Equation (52)
$H_{iso}(\vartheta, c)$	Function $\dfrac{\{F_{iso}(\vartheta, c)^{-1} - 1\}}{c\Gamma_{iso}(c)P_{iso}(\vartheta, c)}$; see Equation (6)
k	Boltzmann's constant
K	Optical constant relating intensities to the Rayleigh ratio
L	Chain contour length
LS	Subscript to indicate the average of a function or parameter obtained in light scattering
M	Molecular weight
M_L	Mass per unit length, M/L
n_{medium}	Refractive index of the medium
n_{solute}	Refractive index of the solute
n_μ	Number fraction of solute component μ
$\tilde{n}$	Ratio n_{solute}/n_{medium}
N_A	Avogadro's constant
$P_{iso}(\vartheta, c)$	Intramolecular structure factor; see Equation (4)
$P_{Hv}(\vartheta, c)$	Intramolecular structure factor for the horizontally polarized component of the scattering with vertically polarized incident light
$P_{Vv}(\vartheta, c)$	Intramolecular structure factor for the vertically polarized component of the scattering with vertically polarized incident light
q	The modulus $q = (4\pi/\lambda)\sin(\vartheta/2)$ wave vector for an isotropic medium
$\mathbf{R}_{aniso}(\vartheta, c)$	Anisotropic component of $\mathbf{R}(\vartheta, c)$
$\mathbf{R}_{iso}(\vartheta, c)$	Isotropic component of $\mathbf{R}(\vartheta, c)$
$\mathbf{R}_{Hv}(\vartheta, c)$	Horizontally polarized component of $\mathbf{R}(\vartheta, c)$ for vertically polarized incident light
$\mathbf{R}_{Vv}(\vartheta, c)$	Vertically polarized component of $\mathbf{R}(\vartheta, c)$ for vertically polarized incident light

$\mathbf{R}(\vartheta, c)$	Excess Rayleigh ratio
R_G^2	Mean-square radius of gyration
R_H	Hydrodynamic radius, defined as $kT/6\pi\eta_s D_T$, with D_T the translational diffusion constant and η_s the solvent viscosity
$S_{iso}(\vartheta, c)$	Total structure factor $\mathbf{R}_{iso}(\vartheta, c)/KcM$; see Equation (7)
w, w_μ	Solute weight fraction; weight fraction of solute component μ
I_{INC}	Intensity of incident light
$I(\vartheta)$	Intensity at scattering angle ϑ
α	Parameter $2\pi R/\lambda$ for spheres of radius R
$\Gamma_{iso}(c)$	Function $\{F_{iso}(0, c)^{-1} - 1\}/c$; see Equation (6)
δ^2	Mean-square molecular optical anisotropy; see Equation (9)
δ_0	Optical anisotropy of a scattering element with molecular weight m_0
ϑ	Scattering angle
λ	Wavelength of light in the scattering medium; λ_0 the same in vacuo
ν	Number concentration of the solute, equal to cN_A/M_n
ρ	Density (wt/vol)
ψ_{solute}	Contrast factor for optically isotropic solute
ψ_μ	Contrast factor for component μ for optically isotropic media

ABBREVIATIONS AND ACRONYMS

FFFC	Flow Field-flow Chromatography
NIST	National Institute of Standards and Technology
PDHS	Poly(di-*n*-hexylsilane)
PMMA	Poly(methyl methacrylate)
PPHS	Poly(phenyl-*n*-hexylsilane)
RGD	Rayleigh–Gans–Debye
SEC	Size Exclusion Chromatography

This discussion of optical particle counting (OPC) points out application areas where the procedure is used to collect data that would not be available otherwise. These areas include determination of particle size distributions from the size data of individual particles, identification of particles that do not fit within a specified size distribution function, and characterizing the particles present in a process of product fluid. The designs, performance, and operation of OPCs for both gasborne and liquidborne particles are discussed. Capabilities and limitations in terms of particle size ranges, counting accuracy, concentration, and so on are pointed out. The primary limitation is related to the fact that OPCs respond not only to the size of the particles, but also to the optical nature of the particles and of the fluid. Data are also affected by the counter design. All respond to a physical and/or chemical property of the particles, as well as to their physical size and morphology. The limitations of OPCs in relation to those factors are considered.

Operational requirements for OPC are pointed out. These include good sample acquisition and handling procedures, consideration of the effects of differences between particle counter designs on reported data, requirements for careful calibration before use and the effects of differences between calibration particles and sampled particles. A brief summary of present national and international standard documents for calibration and operation of these instruments is included. Performance capabilities of current OPCs are summarized and possible future developments are discussed. Performance is considered in comparison with that of other particle measuring procedures.

1 INTRODUCTION

This discussion of OPC describes application areas for the process, the operating principles that are used for both light scattering and light extinction instruments, and the parameters affecting response of these instruments. The performance specifications and capabilities of present day instruments are summarized for measurement of particles suspended in gas or in liquid. Operational requirements in terms of sample acquisition and handling are pointed

out; effects of incorrect procedures are discussed. Calibration procedures and calibration materials are considered as they affect response and differences in response for instruments with design differences. The effects of such design differences are discussed. National and international procedure documents for calibration and operation of OPCs are summarized. Performance capabilities of present day instruments and possible future developments are summarized.

2 HISTORY

The first OPCs were modeled after optical devices developed for detection of airborne chemical and biological warfare agents in the late 1940s. These were based on light scattering systems used for testing high efficiency air filters. A laboratory instrument was produced for the US army and was modified for field use in 1954.[1] At that time, the airborne particle counter was capable of measuring particles in the "diameter" size range of 0.5–20 μm in concentrations up to approximately $3.5 \times 10^6\,m^{-3}$. In 1965, a light extinction counter was developed for measurement of contaminant particles in hydraulic fluids, fuels, mineral oils, and other lubricants. The liquidborne particle counter could measure particles in sizes from 5 to 200 μm in concentrations up to approximately $3.5 \times 10^5\,m^{-3}$.[2] Sensitivities and concentration capabilities have increased significantly for present day instruments and will probably continue to increase in the future. At the same time, the overall bulk and weight of instruments continues to decrease, while new electronic component developments permit more data acquisition, storage, and processing.

3 APPLICATION AREAS

3.1 Determination of Product or Process Particle Size and Quantity

Production and processing of a wide variety of materials are affected by the physical and chemical properties of finely divided materials that are either used in the production operation or are the end product. For example, reaction rates are affected by the available surface area of process materials. Reaction time requirements can be reduced by extending the reactant powder surface by reducing particle size. In handling bulk powders, power requirements to maintain flow through ducts can be reduced by including a range of particle sizes rather than using a single size batch of materials. Process effluents, when exhausted through a stack or in a gas stream, are often controlled by ordinances that specify allowable effluent opacity. The particle size of the material in that effluent will materially affect the visibility of the exhaust plume. This is due to the sensitivity to particle size of the extinction coefficient when particle size approaches the wavelength of visible light.

Many pharmaceutical products are applied by injection of a solids suspension in liquid or by the inhalation of aerosolized dry or liquid particles. The deposition location of such materials is frequently controlled by particle size. Correct operation of much material processing equipment includes verification that the product material particle size is within the specified size range limits. Particle size control may involve dry particle comminution or agglomeration or control of liquid droplet size. Essentially all of the particle size measurement in these application areas can be made either during or after production, using OPCs.

When the required information on particle size and/or quantity is only restricted to the mass or volume of particulate material or to the particle size distribution, OPC may not be the best method to obtain such information. Scattered light measurement of an array of particles, rather than of individual particles, can provide particle size distribution parameters directly. Collection and weighing a sample of the particles can provide particle mass data. However, when information is needed on whether or not all particles in the material being measured fit within the required size distribution limits, single particle sizing and counting by an OPC is frequently the only on-line method that can be used.

3.2 Determination of Fluid Cleanliness or Contamination Level

Ambient atmosphere contamination conditions are of importance in many production areas. Particulate air pollution in residential areas has been a concern for many years, but typical measurement methods did not involve detailed measurement of particle size. Environmental air pollution data for particulate materials has been based on either visibility of emission sources or on mass per unit volume of ambient air. During the 1990s, ambient air pollution in the USA became concerned with control of particles in the respirable size range. Specifications for concentrations of particles ≥ 2.5 μm and ≥ 10 μm are appearing. Further consideration of the physical and chemical effects of particles that are deposited and retained in the lungs can be expected. At this time, the procedures for measuring airborne particulate air pollution still require data in the form of particle mass per unit volume of sampled air. Measurement of particles by filtering an air sample and weighing the collected particles is now in use and is quite effective for particles larger than approximately 5 μm in diameter. However, the smaller particles require much larger air sample volumes

because of their much smaller mass. For this reason, OPCs can generate useful data much faster than the particle collection and weighing method.

In the industries producing electronic, pharmaceutical, optical, and precise mechanical components, the cleanroom production facilities require control of airborne particles to levels where no more than a specified number of submicrometer particles per unit volume of air can be present. Some semiconductor facilities allow no more than ten particles $\geq 0.1\,\mu m$ per cubic meter of air. Deionized water used for cleaning during production is filtered to cleanliness levels of no more than ten particles with diameter $\geq 0.05\,\mu m$ per liter of water. There are no formal specifications for these levels, but production history dictates such cleanliness requirements. That same history indicates that even cleaner production facilities will be required in the future. For operation of precise mechanical or hydraulic control systems, the fluid cleanliness requirements are also based on operational history. The cleanliness level requirements for those fluids are several orders of magnitude less severe than required by the semiconductor industry. In pharmaceutical and medical device production, the Food and Drug Administration (FDA) in the USA and similar agencies in other countries require that both air and water used in production be controlled to appropriate particulate cleanliness levels.

As a result of constant changes in product performance requirements in the semiconductor industry, the need to monitor continuously the cleanliness of the process fluids and of the air environment has resulted in development of some new OPC systems. These devices are used for in situ measurements within production tools during critical production stages. These in situ counters observe the cleanliness of the gases and liquids during such actions as chemical vapor deposition system pressure adjustments, operations, and movement of product elements prior to, during, and following those operations. These gasborne particle counters may be required to operate under extreme temperature and pressure conditions. In some cases, the particle counter sensing element is contained within the tool so that gas flow passes through that element. In other cases, the element is contained within a flow line containing fluids either to or from a process action. An in situ sample, consisting of a portion of the fluid flowing through that line may be measured. Care is required to ensure that the sample portion is sufficient to permit valid characterization of the particles in the total flow.

In a similar development that became important during the 1980s, continuous monitoring of a process or facility cleanliness, has been used to verify that product quality is not affected by contamination generation incidents. An OPC is used to observe fluid flow towards an in-process component or from a potential contamination source. Measurements can be made on a continuous basis or at specified time intervals. Procedures for measurement at a large number of sample points can be established. These procedures can use a single particle counter that receives sequential samples from a series of sample collection points. Each selected sample point feeds fluid into a line that is connected to a central source selection controller that sequentially selects one of the lines and feeds sample to the particle counter for a preselected time interval. The particle counter electronic system and/or external control system can report particle concentration for each of the selected sample points. Data from these measurements can be used to verify that the sample point or an area containing many sample points is in compliance with a fluid cleanliness specification.

4 OPERATING PRINCIPLES OF OPTICAL PARTICLE COUNTERS

4.1 Light Scattering Optical Particle Counters

The basic operation of a light scattering particle counter is shown in Figure 1. The operational part of the counter contains a light source, an optical system for beam shaping to define a sample view volume, a light collection optical system consisting of either lenses or mirrors to collect the scattered light, a photodetector that will convert optical signals to electrical signals, and a signal processing electronic system to convert the electrical signals to information on the size and number of detected particles. Ancillary flow control systems are required to handle the sampled fluid. Light scattering particle counters for liquidborne particles contain the fluid sample stream in transparent tubing, but the optical and electronic systems are essentially identical to those for the airborne particle counters. There is one other difference between some

Figure 1 Light scattering OPC operation. (Adapted from A. Lieberman, *Contamination Control and Cleanrooms: Problems, Engineering Solutions, and Applications*, Van Nostrand Reinhold, New York, 291, 1992.)

airborne particle counters and the liquidborne particle counters. As will be seen later, the capability to detect very small particles increases as the illumination source intensity increases. When a gas laser is used as the light source, the beam intensity in the view volume is normally a very small fraction of the intensity of the beam present in the active cavity between the two mirrors where the gas is located. By replacing one of the containment mirrors with a Brewster's angle window, one of the mirrors can be moved sufficiently far from that panel that a space large enough to pass a gas stream containing the particles to be measured can be exposed to the very high light level present within the active cavity of the laser. This cannot be done when the fluid being sampled is a liquid. The refractive index of the liquid differs sufficiently from that of the gas in the laser and in the external active cavity so that insertion of the liquid degrades the beam in the ''external'' active cavity to the point where signals from particles are decreased significantly. Use of a solid-state diode laser that can emit light at high levels is used when very small particles ($\leq$0.1 μm) in liquid are to be measured.

When no particles are in the sensing volume, only the near-constant level light scattered by fluid molecules enters the collection optical system; the signal output from that source is below the signal level for particle data. As particles pass through the sensing volume, scattered light pulses are generated by each particle. The scattered light pulse pattern depends on the particle size and the ratio of the refractive index of the particle and of the substrate fluid. The refractive index ratio is shown in Equation (1)

$$m = \frac{n_p - ik_p}{n_m} \tag{1}$$

where m is the refractive index ratio, n_p is the real part of the particle refractive index, ik_p is the imaginary (absorption) part of the particle refractive index, and n_m is the refractive index of the fluid medium in which the particle is suspended.

Figure 2 illustrates scattering patterns for particles in several size ranges. The photodetector collects each light pulse that is scattered over the angle in which the collection optical system is operating. The photodetector

Figure 2 Radial intensity of light scattered from particles (spherical water droplets) of various sizes $\alpha = \pi d/\lambda$, scattered light flux polarized I_1 perpendicular and I_2 parallel to the incident light. (a) $\alpha = 0.5$, droplet diameter $d = 0.15$ μm; (b) $\alpha = 3.0$, $d = 1.0$ μm; (c) $\alpha = 4.8$, $d = 1.5$ μm; (d) $\alpha = 6.0$, $d = 2.0$ μm. (Reproduced by special permission from A. Lieberman, *Chem. Eng.*, **73**(2), 97–102 (1967). Copyright (1967) by McGraw-Hill Inc., New York.)

converts the light flux to an electrical signal and feeds that signal to the electronic system of the particle counter. Each pulse amplitude is measured and the pulses within defined amplitude ranges are counted. Pulse amplitude varies as a function of particle size. Since the sampled fluid flow rate is controlled, particle concentration in each size range can be determined.

Operation of the light scattering particle counter is neither as simple as the quick summary above may indicate, nor is it as complicated as might be expected from light scattering theory. Light scattering theory is complex. However, there are some fundamental parameters that affect particle counter response. These include (1) configuration of the illumination and collecting optical systems, summarized as scattering angle; (2) light intensity and wavelength; (3) size of the particle in the sensing volume; (4) the particle refractive index relative to that of the surrounding fluid. The scattering angle controls the quantity of light collected for any particle. For a larger solid angle, more light will be collected. Care is needed in optical design, since counters with larger solid angle collection optical systems can also collect background light reflected from components in the optical system. That background light is essentially optical noise signals that result in false data.

The basic optical system designs used in every light scattering particle counter are shown in Figure 3.[3] Minor differences exist in some instruments. For example, the right angle scattering optical system in the topmost design in Figure 3 has been modified to use a scattering angle

Figure 3 Optical systems for light scattering particle counters. (Adapted from J.R. Hodkinson, J.R. Greenfield, 'Response Calculations for Light Scattering Aerosol Counters', *Appl. Optics*, **4**(11), 1463–1474 (1965).[3])

base that is approximately 120°, rather than 90°. Dual detectors can be used to improve signal levels for better small particle measurement capability. The wide-angle collection system in the middle design uses a set of mirrors to collect the scattered light and to focus that light upon the photodetector.

The derivation of equations defining light scattering is available in the literature and will not be repeated here. Without going into detail, the important parameters that define scattering from a particle include the particle size, the refractive index ratio (including both real and imaginary components) of the particle and of the suspension medium, the illumination wavelength and the solid angle over which the light is collected. The theoretical relationship for light scattering by small particles is shown by Equations (2) and (3), the Rayleigh scattering equations for small particles. Equation (2), for perpendicularly polarized light, shows nearly equal scattering at all angles, while Equation (3), for parallel polarized light, shows scattering equal in intensity to that for perpendicular polarization at $\theta = 0$ rad and $\theta = \pi$ rad, while decreasing to zero at $\theta = 0.5\pi$ rad, as shown for the scattering from a 0.15 μm particle in Figure 2.

$$I_1 = \frac{\alpha^4}{2\pi}\left(\frac{m^2-1}{m^2+2}\right)^2 \tag{2}$$

$$I_2 = \frac{\alpha^4}{2\pi}\left(\frac{m^2-1}{m^2+2}\right)^2 \cos^2\theta \tag{3}$$

where I_1 is the scattered light flux polarized perpendicularly to the incident light, I_2 is the scattered light flux polarized parallel to the incident light, α is the particle circumference divided by the illumination wavelength, m is the particle refractive index, relative to that of the suspension medium, and θ is the scattering angle with respect to the forward direction in degrees.

Scattering theory states that the scattered light signal is a function of the wavelength of the incident light on the particle, the state of polarization of that light, the scattering angle, the refractive index ratio of the particle and the substrate fluid, the particle size, shape, and orientation. Light scattering from particles with dimensions at and below the wavelength of the incident light is identified as Rayleigh scattering. The scattered light signal level is proportional to d^6/λ^4, where d is the particle diameter and λ is the wavelength of the incident light. A small change in particle size changes the scattered light signal significantly. Light scattering from particles with dimensions at and above the wavelength of the incident light is identified as Mie scattering. Figure 2 shows scattered light patterns from particles in both size ranges. Equation (4) is the Mie scattering equation describing scattering for particles of larger size

with vertically polarized light.

$$I_1 = \sum_{m=1}^{\infty} \frac{2m+1}{m(m+1)} [a_m \tau_m(\cos\theta) + b_m \pi_m(\cos\theta)]^2 \quad (4)$$

where a_m and b_m are complex amplitude functions dependent on m and the particle diameter, and π_m and τ_m are angular functions depending on θ.

If a well-collimated beam of light is passed through a fluid, any particle with a light extinction coefficient other than zero that is in the light path will remove light by a combination of scattering out of the direct beam and by absorption. If the absorption part of the particle refractive index (k_p) is zero, light is removed from the beam solely by scattering. The particle extinction coefficient defines the combined effects of scattering and absorption. Beer's law, relating the transmitted and incident light flux, may be written as shown in Equation (5).

$$I = \exp(-Ac_nL) \quad (5)$$

where I is the ratio of light flux after interaction with the particle to incident light flux, A is the projected area of particle(s) illuminated by the incident light, c_n is the numerical particle concentration, and L is the beam pathlength through the effective sensing volume.

At this time, optical particle counters using scattered light signals for particle counting and sizing are in use with illumination sources using incandescent filaments, gas lasers, and solid state lasers. Incandescent filament sources (with their wide range of illumination wavelengths) are used mainly to reduce multivalue response effects. Laser sources are used for measuring particles significantly smaller than 1 μm in diameter. HeNe laser sources (illumination wavelength of some 633 nm) are used in the active or passive cavity mode to permit passing the observed particles through the sensing volume where illumination flux is at a maximum. Argon ion lasers (illumination wavelength of some 400 nm) are used as illumination sources for work with particles somewhat smaller than 0.1 μm in diameter. Solid-state laser sources (illumination wavelength in the range of 650–900 nm) are used as conventional illumination sources supplying high illumination levels. The small size and high reliability of high-power solid-state lasers, that operate without the need for high-voltage power supplies, has resulted in their increasingly widespread application. Particle counters using polychromatic light and large solid angle light collection systems produce the desired single-valued response, but sensitivity for small particle measurement is decreased and background noise must be minimized.

As of 1996, both airborne and liquidborne particles of 50 nm and larger could be counted and sized efficiently. Most light scattering optical designs use wide-angle light collection systems to maximize particle sizing resolution capability and to minimize multivalued response where the signal both increases and decreases as measured particle size increases. Right angle optical systems are widely used with Mangin mirrors (concave spherical mirrors that can collect and focus light to the photodetector) collecting the light over a total angle of $90° \pm 45°$. This system is now used for counting and sizing particles in the size range from 50 nm and larger. There are many optical designs used for particle counting and sizing instruments at this time. A more detailed discussion on design and operation of light scattering OPCs is given in a recent ISO (International Organization for Standardization) standard.[5] This discussion also covers air flow system design and operation to ensure that the fluid sample stream is completely within the sensing zone so that all particles are adequately illuminated.

The variety of designs and components result in significant differences in response when different instruments are used to characterize the same particle samples. Data variability is reduced by the following procedures:

1. Minimize differences in the optical designs of the instruments used.
2. Calibrate all instruments, preferably with certified reference particles with traceable dimensions, with all instruments using the same calibration procedures and materials.
3. Do not use instruments beyond their capabilities of particle size range, fluid flow rate, or environmental conditions.

4.2 Light Extinction Optical Particle Counters

The optical systems used for light extinction particle counters illuminate a small volume of flowing fluid and characterize particle content of that fluid by the reduction in the amount of light passing through that volume due to the particle(s) within the flowing fluid. The light beam is directed to the photodetector element. The fluid stream flows through a region of uniform illumination. When there are no particles in the illuminated volume of fluid, a constant signal is received by the photodetector. As a particle passes through the sensing volume, some light is removed by the particle as a result of scattering out of the direct beam and/or by absorption by the particle. Thus, a signal proportional to a function of particle size is generated. For particles smaller than approximately 5 μm, that signal varies with the refractive index of the particle. For larger particles the extinction coefficient stabilizes at a value of two, regardless of the refractive index of the particle. For this reason, differences in optical properties of the calibration particles and

the measured particles do not produce as great signal differences as occur for particles smaller than 5 μm. The scattering coefficient is strongly dependent on the particle/fluid refractive index ratio, especially for particles smaller than 5 μm in diameter. These instruments are used mainly for measurement of particles suspended in liquid. Some extinction instruments are also used for sizing and counting dry particles that are large enough so that they can be passed through the sensing volume by dropping them from a vibratory feeder and allowing gravity to move them through the light beam at a velocity sufficient to keep the residence time to no more than 50 μs or so. Figure 4 shows the optical system for an extinction optical counter that observes the full liquid sample stream. A transparent rectangular or circular flow tube defines the sensing volume cross-sectional area; the height of the sensing volume is defined by the configuration of the illumination beam. The beam height is normally a few tens of micrometers and the beam width extends across the full liquid sample stream; many systems have areas in the range of 0.5–1.0 cm^2.

Figure 4 Optical systems for light extinction particle counter. (Reproduced by permission of Particle Measuring Systems, Inc.)

Essentially the same parameters affect the response of the OPC using light extinction as the counter using light scattering. The optical properties of the particle/fluid system affect the extinction system response markedly, particularly for small particles. This is due mainly to the fact that the refractive indices of many process and product liquids are frequently similar to the refractive index of the particles being measured. However, as the measured particle size increases above 5 μm, the extinction coefficient stabilizes at a value of 2.0 for essentially all refractive indices, reducing that cause of error. This effect is shown in Figure 5.[6] The projected area of the particle affects the amount of light removed from the direct beam and its orientation as it passes through the sensing volume in a manner similar to the effects pointed out for light scattering systems. The response curve for the extinction optical counter is a power function that varies from approximately the fourth power of particle size for particles in the micrometer size range and decreases to approximately the second power for particles larger than approximately 5 μm in diameter. Most light extinction OPCs use an optical system that observes light that is nearly a totally parallel beam. The beam intensity through the sensing volume is close to uniform, with minimum differences due to the normally

Figure 5 Theoretical and experimental light extinction coefficients. (a) Mie theory, (b) measured data. (Adapted from J.R. Hodkinson, 'The Optical Measurement of Aerosols', in *Aerosol Science*, ed. C.N. Davies, Academic Press, New York, 1966.[6])

Gaussian intensity distribution in a laser beam or the intensity variations from a ribbon filament incandescent light source. For this reason, particle sizing resolution for light extinction OPCs is excellent unless assembly or alignment problems cause excessive variation of light intensity in the sensing volume. This characteristic of extinction systems improves data reliability, particularly when measuring particles with wide variations in shape factor or composition.

5 PERFORMANCE SPECIFICATIONS FOR OPTICAL PARTICLE COUNTERS AND FACTORS AFFECTING PERFORMANCE

5.1 Sample Fluid Flow Rate

Since much of the data desired from OPC applications involves particle concentrations, accurate sampled fluid

flow rate data are a requirement. Specifications for such data require measurement of fluid flow with an external flow-measuring device that will not generate excessive pressure drop for gasborne particle counters. For liquidborne particle counters, a flow measuring device that can be operated to avoid indication of multiphase (gas and liquid) fluids as single phase fluids is necessary.

5.2 Background Noise Count Rate

When seeking maximum size sensitivity, OPCs may be operated with electronic systems set at maximum gain. In this situation, random electronic or optical noise may generate pulses large enough so that they can be reported as signals from small particles. In this case, erroneous data are generated that indicate more particles than are actually present in the measured sample. Operating the particle counter with particle-free fluid entering the sensing volume can identify this situation. Use of a filter with pore size no more than half the size of the smallest measurable particle on the fluid flow line can satisfy this requirement. The counter can be operated in this manner for time periods up to 30 min for two or three measurements and the observed noise count rate can be stated.

5.3 Particle Sizing Accuracy and Size Measurement Range

The need for sufficient data to provide statistical validity in characterizing particles has resulted in development of particle counters that can count and size particles of the smallest possible size with good accuracy and can portray the size distribution over as much as possible of the actual size range of the sample being measured. For light scattering particle counters used for either gasborne or liquidborne particles, size measurement of 0.05-μm particles is possible with several commercially available instruments. It is possible to obtain size data up to as much as 100 times the smallest possible size measurement. For light extinction OPCs, calibration particles $\geq 1\,\mu m$ can be measured. The other end of the dynamic range capability is at 100 times the smallest size. The particle sizing accuracy should be no less than 95%. These data are based on the modal diameter stated for a batch of calibration particles that have been measured by an accepted particle sizing procedure.

5.4 Particle Size Resolution

Size resolution is the capability to differentiate between particles of nearly the same size. Accepted sizing resolution is the ability to differentiate between particles that differ by more than 5% in diameter. This value is determined by measuring a batch of near-monodisperse calibration particles that have been measured by a reference method that has provided data on the modal size and the relative standard deviation of sizes. The reported relative standard deviation should be no more than 5% greater than the specified standard deviation from the reference method data.

5.5 Particle Counting Accuracy

Although particle counting accuracy is considered a requirement mainly for determination of particle concentration when the quantity of particles is of concern, this is also a problem when establishing particle size distribution if any of the size ranges being measured do not report the particle population accurately. The particle counting accuracy is verified by counting aliquot samples of a particle suspension by the particle counter under test and by a referee method. The referee method can be an instrument other than the OPC or it can be an OPC that has been verified as producing accurate particle count data over the size range of concern. Counting accuracy requirements are typically stated as $50\% \pm 5\%$ at the most sensitive size capability and $100\% \pm 5\%$ for all particle sizes at least 1.5 times larger than that most sensitive size.

5.6 Particle Concentration Limits

The maximum concentration that can be accurately measured by any particle counter is limited by the accepted coincidence error. This error is due to the probability that more than one particle is present in the sensing volume at any time. The error level is a function of the physical dimensions of the sensing volume, the actual particle concentration within the sample being measured, and the particle size distribution of the particles in that sample. For samples where all particles are so small as to be insignificant in dimensions in comparison to

Figure 6 Coincidence effect on reported concentration accuracy. (Adapted from A. Lieberman, *Contamination Control and Cleanrooms: Problems, Engineering Solutions, and Applications*, Van Nostrand Reinhold, New York, 357, 1992.)

those of the sensing volume, the probability of more than one particle being present within a defined volume can be calculated directly from statistical theory,[7] as shown in Figure 6.[8] Figure 6 shows the ratio of reported concentrations to true concentrations for two optical liquidborne particle counters; one had a rated concentration capability of 12 000 particles per mL and the other a capability of 3000 particles per mL. However, the electronic circuitry in any particle counter cannot respond to the presence of a particle entering the sensing volume until the signal from a previous particle in the sensing volume has decreased to the system reset level. When particles are so large that their size is significant in comparison with a sensing volume dimension, the presence of such a particle causes an effective increase in the sensing volume dimension, as shown in Figure 7.[9] The presence of large particles in the sample decreases the reported particle concentration limit more than expected from the calculation of the probability of coincident small particles in the sensing volume alone.

5.7 Instrument Stability and Verification

This all-inclusive performance requirement is handled by ensuring that the calibration procedure fits the application requirements and that calibration is carried out at no more than the maximum time interval specified for the particle counter in use or the regulatory document specified for the application where the measurements are being made. Details of calibration procedures are provided below where a summary of some national and international standard documents and their sources are summarized. Not all of the existing standard documents are included, but those indicated cover essentially all of the information required to carry out the procedures and operations that will aid in generating valid data for particle counting.

6 STANDARD DOCUMENTS FOR PERFORMANCE AND OPERATION

6.1 Gasborne Particle Counter Performance Documents

1. ASTM F328: Determining Counting and Sizing Accuracy of an Airborne Particle Counter Using Near-monodisperse Spherical Particles (ASTM, American Society for Testing and Materials)
2. ASTM F649: Standard Practice for Secondary Calibration of Airborne Particle Counters Using Comparison Procedures (ASTM)
3. BS 3406: Part 7. Determination of Particle Size Distribution: Recommendations for Single Particle Light Interaction Methods (BSI, British Standards Institution)
4. ISO 13323-2: Determination of Particle Size Distribution–Single Particle Light Interaction Methods–Part 2: Light Scattering Single Particle Light Interaction Devices Design, Performance Specifications, and Operation Requirements (ISO)
5. JIS B9921: Light Scattering Automatic Particle Counter (JIS, Japanese Industrial Standards)
6. VDI 3489(3): Particulate Matter Measurement: Methods for Characterization and Monitoring of Test Aerosols: Optical Particle Counter (VDI, Verein Deutscher Ingenieure)

6.2 Gasborne Particle Counter Operation Documents

1. ASTM F50: Continuous Sizing and Counting of Airborne Particles in Dust-controlled Areas and Clean Rooms Using Instruments Capable of Detecting Single Submicrometer and Larger Particles (ASTM)
2. BS 5295(4): Environmental Cleanliness in Enclosed Spaces. 4. Specification for Monitoring Clean Rooms and Clean Air Devices to Prove Continued Compliance with BS 5295: Part 1 (BSI)
3. Federal Standard 209E: Airborne Particulate Cleanliness Classes in Cleanrooms and Clean Zones, Appendix B (IEST, Institute of Environmental Sciences and Technology)
4. ISO 14644-3: Cleanroom Measurements and Metrology (ISO)

5. JIS B9920: Measuring Methods for Airborne Particles in Clean Rooms and Evaluating Methods for Air Cleanliness of Clean Rooms (JIS)

6.3 Liquidborne Particle Counter Performance Documents

1. ASTM F658: Defining Size Calibration, Resolution, and Counting Accuracy of a Liquid-borne Particle Counter (ASTM)
2. ANSI/NFPA T2.9.6R2: NIST (National Institute of Standards and Technology) Traceable Calibration Method for Liquid Automatic Particle Counters (ANSI, American National Standards Institute)
3. DIN 50432: Part 2, Test Method for Particle Analysis in Liquids: Determination of Particles with Automatic Particle Counter (DIN, Deutsches Institut fur Normung)
4. JIS B 9925: Light Scattering Automatic Particle Counter for Liquid (JIS)
5. ISO 13323-3: Determination of Particle Size Distribution – Single Particle Light Interaction Methods – Part 3: Light Extinction Single Particle Light Interaction Devices Design, Performance Specifications, and Operation Requirements (ISO)
6. ISO 11171: Hydraulic Fluid Power – Calibration of Liquid Automatic Particle Counters (ISO)

6.4 Liquidborne Particle Counter Operation Documents

1. JIS K 0554: Testing Method for Concentration of Fine Particles in Highly Purified Water (JIS)
2. SEMI C1-88: Calibration & Measurement Methods for Particles in Liquids (SEMI, Semiconductor Equipment Manufacturers International)
3. ANSI B93-73M: In-line Liquid Automatic Particle Counting Systems – Method of validation (ANSI)

7 OPERATIONAL REQUIREMENTS FOR PARTICLE COUNTING

7.1 Sample Acquisition, Handling, and Storage Requirements

Particle counting is used to carry out three types of particle measurement. The particle size and size distribution of samples from bulk powders are defined; the particulate content of ambient air or liquid is measured; the particulate content of process or product gas or liquid is measured. The three application areas have one common requirement that must be satisfied before any useful data can be collected. This is the requirement that a valid sample be acquired and that the sample be handled so that no data are collected that have been generated by improper sample handling procedures. The procedures and the reasons for these procedures will be discussed for the three application areas.

7.1.1 Bulk Powder Sampling Procedures

When particle counting is used to make measurements of bulk powders, the objective is to determine a particle size distribution and to define outlier particles that are either too small or too large to fit into the size distribution correctly. During transport or storage, the particles in the powder will frequently pack in such a way that portions of the powder bulk will contain particles with a size distribution that differs from the original distribution. As an example, vibration may cause small particles to settle towards the bottom of the powder container by falling through the interstices between large particles. Even so, it is still necessary to procure a representative sample of the total material. This may require special care in taking samples from a container where polydisperse material is stored. To sample correctly, an accepted procedure should be followed including subsample preparation via spinning riffler or other accepted powder subdivision procedure.[10] This procedure may require more than one repetition to produce samples small enough for measurement by OPC. The sample is then dispersed into

the fluid in which it will be measured. It should be followed immediately by measurement of the particles suspended in that fluid. If samples are dispersed into liquid, stirring or agitation is required before measurement of the suspended particles is carried out. This dispersion should be carried out in such a way that a minimum quantity of air is aspirated into the suspension. If any gas is present, gas bubbles will form and may be interpreted as particles. Transport of fluid suspension in ducts or tubes should be carried out with tubing that does not contain any sharp bends or short radius elbows. These can cause deposition of particles due to centrifugal force during transit through the tubing. Excessive residence time (more than 3 min in gas or 5 min in liquid) in the tubing should be avoided. Large particles may be lost to tube walls via gravitational settling or turbulent flow impaction losses. Small particles may be lost via diffusion to the tubing walls or by agglomeration with other particles. Small dry powder samples can be stored in closed containers for long time periods with no significant changes in the samples. Powders dispersed in gas cannot be stored longer than a few minutes unless the particles are so small that diffusion by the gas molecules will keep the particles dispersed until size measurements are made. For particles in liquids, samples stored for more than 30 min or so will require stirring or agitation before particle size or concentration measurements are made unless no particles larger than 5 μm are in the powder.

7.1.2 Ambient Air Sampling Procedures

Ambient air sampling procedures are often specified by regional air pollution control agencies. Until the 1980–1990 period, the requirements for air pollution control of inert particulate materials were based only on mass loading of total airborne particles with no specifications as to the size of those particles. Most requirements for acceptable particulate levels in the ambient air are expressed in terms of milligrams per cubic meter. The particle population for those levels is beyond the detection capability of all but a few research type OPCs. In the late 1970s, information from industrial hygiene studies and research on particulate material retention in the respiratory tract generated concern about the particle size of inert airborne particles. From that time, the EPA (Environmental Protection Agency) in the USA, along with similar agencies in other countries, began specifying that data on the mass loading of particles $\geq$2.5 μm and $\geq$10 μm should be collected. For this reason, it can be expected that ambient air measurement using OPC and sizing may also become a requirement. These measurements will require sample acquisition procedures that collect particles with sizes $\geq$2.5 μm and $\geq$10 μm in such a way that the concentration of those particles can be defined correctly. Isokinetic sampling or an equivalent procedure will be required for airborne particles larger than approximately 5 μm. Sample storage for particles to be measured using an OPC is not anticipated. The optical system will be incorporated with the sampling system for immediate measurement with data either stored or transmitted electronically to a central data processing facility.

For air flow sampling isokinetic sampling is required for all particles larger than approximately 5 μm; for liquid flow sampling, isokinetic sampling is required for particles larger than approximately 10 μm. Isokinetic sampling requires that the sample probe inlet flow is at the same velocity as that of the sampled fluid flow. In areas where the sampled fluid flow rate may vary, then isoaxial sampling is recommended. In areas where sampled fluid flow direction and three-dimensional velocity may vary in a random manner, then a sample probe that faces upward is recommended so that ''large'' particles will be sampled with maximum accuracy. In essentially all areas where processor product fluid cleanliness data are of concern, the OPC has been widely used. In production areas for the electronics industry and the pharmaceutical industry, the standard procedures specify OPC instruments for particle size and concentration data production. For areas where particles smaller than 0.1 μm are of concern, scanning electron microscopy measurement of particles that have been collected from fluid samples is also used. However, the higher capital costs, labor time, and delay between sample acquisition and data availability connected with that method has resulted in use of OPCs in many areas where measurement of particles $\geq$0.05 μm is required.

7.1.3 Process and Product Fluid Sampling Procedures

Many products presently in common use are based upon complex technological components. Most of the operating parts of computers, automobiles, communication systems, and optical devices are components that must be produced in clean areas where particulate contamination in the air in production areas would cause immediate or later failures. Pharmaceutical and other health care products such as injectable liquids and medical devices must be produced in areas where both viable and inert particle content of the environmental air and the process liquids are carefully controlled. Hydraulic fluid power control systems contain components with moving parts operating with very small clearances. Particulate contaminants in the hydraulic fluid must be controlled to minimize control action errors. Performance of optical components, such as high-accuracy mirrors, long-range lens systems, film for use in medical applications of electron microscopy, and so on, can be degraded if contaminant particles in micrometer sizes are deposited upon those critical surfaces

during production. Most automobile painting facilities are now operating with ventilation air systems containing high-efficiency filters to prevent any atmospheric particulate debris from degrading those surfaces by deposition upon the still-wet paint. Air cleanliness is of paramount importance in essentially all areas where particle contaminants may degrade product quality. The facilities where particle-sensitive production occurs, known as ''cleanrooms'' are kept as clean as possible by controlling the ventilation air cleanliness with a filter which has a particle removal efficiency from 99.97% for particles $\geq$0.3 μm (for routine operations) to removal efficiencies of 99.9999% for particles $\geq$0.1 μm for semiconductor production. Unidirectional airflow moving at a velocity of 0.5 m s^{-1} is used in very clean areas. The concentration of particles $\geq$ 0.1 μm in some work spaces is kept at levels of no more than 100 m^{-3}. Air flow in the most sensitive areas is controlled so that air movement is unidirectional with minimum recirculation of potentially contaminated air in the cleanroom. The objective is to verify that the particle concentration in that air is less than 10–100 particles per cubic meter. Air sampling in critical areas is continuous, with particle counters sampling air at 0.47 m^3 s^{-1} and sizing and counting all particles $\geq$0.1 μm in diameter. The particle counter sample line inlet faces into the air-flow path and the inlet velocity is controlled so that isokinetic sampling is assured. In areas where products are not as sensitive as the semiconductor products, the air flow direction and three-dimensional velocity may be random; a sample probe that faces upward is recommended so that ''large'' (>5 μm) particles will be sampled with minimum loss. If the particle counter is not located directly in the sampled air flow, a sample probe may be located at the end of a sample transport tube. Experience has shown that residence time in the tube must be minimized and that turbulent flow is desired to minimize gravitational losses. For valid measurement of particles smaller than 2 μm, tubing lengths up to 30 m can be used with the Reynolds number for the gas flow maintained between 5000 and 25 000. For valid measurement of particles of 5 μm and larger, tubing lengths should not exceed 2 m. The same limitations on the Reynolds number for air flow apply for the larger particles. These limitations ensure that laminar air flow is not present in the tubes and that turbulence is not so great that excessive particle impaction occurs upon the tubing walls.

When product or process liquids are to be examined for particle content, the sampled liquid will be in a process or product flow line or batch samples already in containers will be examined. Acquisition of samples from a line containing flowing liquid requires that two factors be considered. First, it is necessary that samples be procured from a line that is completely filled with liquid. Sampling from zones of mixed gas and liquid should be avoided. The bubble content of liquid from such areas cannot be anticipated and the quantity of liquid removed for each sample is difficult to measure with any accuracy. The second requirement is that the sample should be removed so that the removal does not cause loss of any particles due to centrifugal force produced by excessive curvature of the sample flow path. When process or product liquids are to be measured for particle content, the sampled liquid will either be in a flow line, or batch samples will be examined. Acquisition of samples from a flowing line requires that a sample probe line be inserted into the sampled line. The sample probe line should not be configured so that the sampled liquid is moved through a short radius-of-curvature elbow or a line that imposes centrifugal force upon the particles in the sampled liquid. Figure 8 illustrates two recommended configurations and one less desirable configuration for liquid flow line sampling. The same configuration should be considered for possible use in gas flow sampling from lines where high velocity or high pressure gas is to be sampled. As previously mentioned, sampling for measurement of large particles is best accomplished with isokinetic sample flow control. After a flow line sample has been passed through the sensing volume of the OPC, disposal or return of the measured sample to the process line may be required. Care is required in disposal of liquids that may be hazardous. Consideration of the Material Safety Data Sheet (MSDS) requirements for handling as well as local and other municipal safety requirements in

Figure 8 Sidestream sample probe configurations. (Adapted from A. Lieberman, *Contamination Control and Cleanrooms: Problems, Engineering Solutions, and Applications*, Van Nostrand Reinhold, New York, 398, 1992.)

handling process and product liquids must be part of the sample handling and disposal protocol.

If batch samples are to be measured, these samples should be in containers that can be placed in a sample feeder attached or attachable to the OPC. Use of ''round-bottom'' sample containers is suggested, whenever possible, so that any necessary stirring does not result in particles being deposited upon vertical container walls. Before samples are measured, the sample container should be shaken, or otherwise agitated, to ensure that particles are randomly distributed in the container, rather than settled at the container bottom after long periods of storage, or deposited upon container walls by centrifugal force from stirring. Before any samples are measured by removal from a container, dissolved gases should be removed by exposing the liquid to low-level ultrasonic vibration and to vacuum just before samples are withdrawn from the container. A sample withdrawal tube should be located with its inlet located in the lower third of the container. Sample volumes sufficient to produce a particle count of 1000 to 10 000 are suggested. The concentration of particles should be at a level where three replicate aliquot samples can be acquired from the container and no more than approximately 75% of the total container volume is removed from the container during this process. Note the particle count for each of the aliquot samples. The count for any sample should not differ by more than 20% from the average for all three samples. The same concern for proper disposal of measured samples and residual liquids in the sample containers and treatment of the containers is required as was used for liquids from process of product line sample disposal.

7.1.4 Inter- and Intrainstrument Variability and Means of Minimizing Differences

As was shown in Figure 2, the scattered light intensity varies markedly with scattering angle for all particles larger than approximately 0.3 μm. In addition, Figure 3 points out the differing optical system bases for light scattering particle counters. Considering both situations, it is apparent that the same size and type of particle measured by two dissimilar light scattering OPCs will produce different data. Light extinction OPCs use optical systems with collection angles that may be less than 5°, but scattered light directed out of that small angle will vary with the wavelength of the illumination source for the counter. Extinction counters that are in use now and probably for another decade or so use incandescent filament sources, gas lasers, and solid-state laser illumination sources with significant differences in light wavelengths. For this reason alone, when the calibration particles differ from the particle being measured, instruments with different light sources will generate different data from the measured particles. Although the differences in data are primarily in the reported particle sizes, the effect of reported size differences also affects the reported particle concentration when data on particle size distribution or on particle concentration in a specified size range is required. There are also differences in data from same model OPCs produced by any manufacturer. These arise from the fact that tolerances in manufacturing drawings may be enough to result in scattering angles that can differ slightly between instruments of the same model from any manufacturer. These phenomena may result in production of particle size data differing by no more than a few percent. However, if incorrect calibration materials or procedures are used, or if the instrument calibration is not current, then significant data differences can be expected between instruments. Procedures to minimize interinstrument variability can be summarized as:

1. Use instruments that are similar in design and operation.
2. Make sure that the operators are familiar with instrument operation.
3. Specify a calibration procedure and use calibration particles similar to the particles to be measured.
4. Verify that every phase of the calibration is current.
5. Operate the instrument within its specified capabilities for particle size and concentration.
6. Establish a consistent sample handling protocol

7.2 Calibration Specifications and Procedures

7.2.1 Calibration Specifications

The parameters to be calibrated for any OPC include:

1. Maximum optical and electronic noise pulse generation rate. This rate should be no more than 3–5% of the rate anticipated for the minimum particle counting rate.
2. Fluid sample flow rate. This should be established with minimum accuracy of 95% of the reported inlet sample flow rate.
3. Particle sizing accuracy. This parameter should be established with minimum accuracy of 95% of the smallest reported particle size, based on measuring monodisperse calibration particles with diameters defined by a recognized documented method.
4. Particle sizing resolution. This parameter is the increase in reported relative standard deviation of a monodisperse calibration particle suspension and shall be no more than 5% greater than the stated relative standard deviation of the calibration particles.

5. Particle counting efficiency. This parameter defines the accuracy with which the OPC counts individual particles at the minimum detectable size and at all larger defined sizes. The counting accuracy for monodisperse particles at the minimum detectable size should be 50% ± 10% and the counting accuracy for particles at least 1.5 times larger than the minimum detectable size should be 100% ± 10%.
6. Particle concentration limit. This parameter defines the maximum concentration where the probability of multiple particles within the sensing volume is no more than 10%.

7.2.2 Calibration Procedures

Brief descriptions of calibration procedures for OPCs will be provided here. For further details, the reader is referred to the documents listed in section 6 of this discussion. Section 6.1 lists some calibration procedures for gasborne particle counter performance verification. Section 6.2 lists some operation procedures for gasborne particle counters. Section 6.3 lists some calibration procedures for liquidborne particle counter performance verification. Section 6.4 lists procedures for liquidborne particle counter operation. Complete descriptions of these procedures will not be provided here; the reader is directed to the documented procedures of section 6. Sources for the procedures are also provided in section 6.

7.2.2.1 Performance Calibration Procedures for Optical Particle Counters

Sample Flow Rate. To report suspended particle concentration accurately, the measured fluid sample flow rate into the counter must be defined accurately. Flow is measured by a volumetric flow measurement device that operates with low-pressure drop that will not degrade performance of the counter flow control system. If a mass flowmeter is used for calibration of the sample flow rate for a gasborne particle counter, then correction to the specified ambient or standard temperature and pressure conditions must be calculated and used in the concentration determination. Sample flow rate should be defined with a minimum accuracy of 95%.

Noise Count Rate. Noise count rate calibration is carried out to ensure that data, particularly in the smallest size range capability of the counter, are generated by particles rather than by background noise pulses from the electronics or optical systems. The noise count rate measurement is made by operating the particle counter with particle-free fluid moving through the sensing volume. Recording the noise count rate for a specified time period provides valid data. The noise count rate should not exceed 5% of the count rate anticipated for the anticipated particle count rate.

Particle Sizing Accuracy. Although the particle counter may be used to characterize particles containing materials that vary in shape and composition, a consistent response to selected calibration particles is required. For many OPC sizing accuracy calibrations, isotropic spherical latex particles are most often used for this purpose. A suspension is generated and the modal pulse amplitude of the pulses produced from a batch of particles of known size and relative standard deviation is defined as the signal level for particles of the same size as that batch of calibration particles. Since the OPC response varies significantly with refractive index of the particles being measured, calibration with latex spheres with a refractive index of 1.6 and with no absorption may cause a problem when the counter is to be used for measurement of particles with different optical properties. In this situation, a solution of a known concentration of material with properties similar to those of the material to be measured can be prepared in a liquid with appreciable vapor pressure. Monodisperse droplets can be generated using a vibrating orifice droplet generator; short exposure to air will cause the liquid to evaporate from the droplet leaving a residual particle of the desired physical characteristics. Knowing the size of the monodisperse droplets and the solution concentration, the size of the residual droplet can be calculated and used for calibration purposes. Alternately, polydisperse particles with optical properties similar to the particles to be measured can be used if the particle size distribution for that suspension is known.

Particle Sizing Resolution. This parameter is determined after particle size calibration is carried out for the full size range of the counter being calibrated. If a suitable pulse height analyzer is available, either as an external instrument, or incorporated in the electronic section of the counter being calibrated, data obtained during size calibration can be used to define the relative standard deviation of the pulse height distribution when the monodisperse latex calibration particles are measured. Pulse size data for particles at least twice the size of the lower sizing limit of the counter can be used. These data are converted to values for the average particle size and standard deviation values. The increase (if any) in relative standard deviation, compared to the labeled value of the calibration particles, is reported as the particle size resolution of the counter being calibrated. A maximum reported relative standard deviation no more than 10% greater than that of the calibration particles is acceptable, but resolution values in the 5% range are preferred.

Particle Counting Efficiency. Particle counting efficiency is affected by several factors. If sample flow is not completely contained within the defined sensing volume, some portion of the particles in the sample will not be seen. If sizing resolution is poor, some particles smaller than the lower size boundary of any size range will be reported as being within that range, resulting in excessive particle count data in that range. Counting efficiency for an OPC is determined by producing a well-mixed suspension of particles in a closed chamber. Samples are withdrawn from a single location in the chamber by the counter being calibrated and by a reference particle counting device. That reference device is one that is known to have 100% counting efficiency for the smallest particles in the test suspension. Sample transport to both the counter being calibrated and the reference system uses sample handling systems that are designed so that particle losses during transit from the chamber to both instruments are either negligible or identical. Samples are counted by both instruments and counting efficiency of the calibrated counter is defined as the ratio of the data reported by that counter to the data reported by the reference instrument. Primary counting efficiency data are obtained using suspensions of monodisperse particles. Counting efficiency for specific materials can be procured with a suspension of polydisperse test particles. The counting efficiency so obtained may vary from the primary counting efficiency data.

Particle Concentration Limit. If a high particle concentration may be present in the sampled fluid, more than one particle may be present in the sensing volume at any time. Even if the concentration is known to be no more than the concentration equivalent to one particle per sensing volume, then the fact that particle distribution in the sample is random, rather than uniform, will result in more than one particle being present in the sensing volume at some time. Several small particles may be reported as a single larger particle, resulting in a report of larger and fewer particles than are actually present. As sample concentration increases, the probability of coincidence error also increases. The maximum recommended concentration accepted by many organizations is that where the coincidence error is no more than 10%. The particle concentration limit is determined by producing a series of particle suspensions carefully diluted and sampled by the instrument being calibrated. The initial sample concentration should be in the range between the maximum recommended concentration and twice that level. The diluted suspensions are prepared so that the concentration of each succeeding suspension is reduced by a constant known factor from that of the previous suspension. Dilution ratios between 0.1 and 2 can be selected. The reported concentration of each succeeding suspension is recorded and the reported concentration of that suspension is compared to that of the previous suspension. At concentrations above the maximum recommended concentration capability, the ratio of counts in successive suspensions will be less than the dilution ratio. This indicates that coincident particles were present in the more concentrated suspension. When both suspension concentrations are below the recommended maximum concentration limit, the reported concentration ratio for two succeeding suspensions will be equivalent (95% to 105%) to the dilution ratio. The concentration of the more concentrated suspension at this point is the recommended maximum particle concentration for that particle counter.

7.2.2.2 Operational Procedures for Airborne Particle Counters After the particle counter has been calibrated, it is ready to size and count particles in the sample that is to be measured. However, there are some precautions required to maintain the sample with no artifact introduction or particle loss. The requirement for isokinetic sampling in gases has been discussed previously and will not be repeated here. The procedures for isokinetic sampling involve measurement of the sampled gas stream velocity, knowledge of the particle counter inlet flow rate and selection of an inlet probe dimension that will establish the sample probe inlet velocity at the sampled gas velocity. Even when the particles to be counted are so small so that anisokinetic sampling will not cause particle count errors, isokinetic sampling may still be required to ensure that the sampled gas source can be identified exactly. When air to be sampled is not moving at a constant velocity or is static, isokinetic sampling cannot be used. The primary concern in this situation is collection of particles $\geq 5\,\mu m$ with minimum losses. Figure 9 describes the particle size and sampled air-flow parameters that allow accurate sampling for a vertical thin-wall sample probe with an upward-facing inlet.[11] Sampler inlet efficiency is shown as affected by the Stokes number (defined here as the ratio of the stopping distance of a particle to the diameter of the sample probe inlet) and relative settling velocity of the sampled particle (the ratio of the particle settling velocity in still air to the sample probe inlet velocity).

In many air sampling operations for cleanroom performance verification, intermittent sample collection from a number of locations may be required to verify that tool and processing operations are not producing contaminant particles. In this situation, economic and space limitations may dictate a sampling procedure wherein a single OPC is connected to a sampling manifold system. This system consists of sample tubing from each sample point to the manifold system that directs samples to the particle

Figure 9 Sample tube efficiency in turbulent or still air. (Reproduced by permission of American Industrial Hygiene Association from J.K. Agarwal, B.Y.H. Liu, *Am. Ind. Hyg. Assoc. J.*, **41**, 191–197 (1980).[11])

counter inlet with minimum loss in the transfer process. However, the sample tubes must be configured correctly so there is minimum particle loss in the tubing during transit to the manifold and particle counter. This means that the tubing should not be so long that residence time in the tube will cause excessive loss of particles larger than 1–2 μm due to deposition caused by gravitational or turbulence effects. The tubing should not have an excessively small diameter (<6 mm) or pressure drop in the tubing will reduce the flow excessively. The tubing should have no bends with radius of curvature less than 15 cm to avoid centrifugal effects at the bend. The tubing material should be selected to minimize electrostatic charge by triboelectric effects. Stainless steel tubing is best if permanent installations are considered and cost is acceptable. Reactive metal (copper or aluminum) should not be used. Conductive polymer tubing with conductivity equivalent to that of plasticized polyvinyl chloride is recommended when sample line location or configuration may be modified as product or process changes dictate. Plasticized polyvinyl chloride is quite useful for handling particulate suspensions in many fluids, but even small quantities of the dioctyl phthalate plasticizer vapor may cause problems in product performance. Fluorocarbon or glass tubing is not recommended because of the electrostatic charge generated and retained by this tubing from aerosol flow.

7.2.2.3 Operational Calibration Procedures for Liquidborne Particle Counters The calibration procedures are summarized briefly here. For full details refer to the documents listed in section 6.

Sample Flow Rate and Volume. Liquidborne particle counters measure particles in liquid samples in several possible modes. The sample may be aspirated into the counter sensing volume by placing a batch sample container under the sensing volume, with a tube leading from the container to the sensing volume, reducing the pressure in the sensing volume, and drawing a sample through the sensing volume with subsequent disposal of the tested liquid. The sample may be forced through the sensing volume by increasing the pressure in the sample container to force the liquid upward through the sensing volume. A flowing stream of sample liquid may be forced through the sensing volume by placing a sample line inlet in that flowing stream with the sample line outlet connected to the counter sensing volume.

When aspirating samples from a sample container, the contents of that container must be well mixed before samples are measured. The aspiration process must not reduce the static pressure on the sensing volume to the point where dissolved gas in the liquid will form bubbles or to the point where the pressure in the sensing volume is below the vapor pressure of the liquid at the measurement temperature. When the samples are moved through the sensing volume by pressurizing the sample container, the pressure must be maintained at a constant level or the flow rate will change; this may cause the signal pulses to become so short that erroneous sizes are reported from those pulses. If the flow rate decreases excessively, then the liquid velocity upward through the sample tube to the sensing volume may decrease to the point where the gravitational settling velocity of large particles in that sample may exceed the upward velocity, with the result that no large particles move through the sensing volume. Figure 10 illustrates a pressure feeder for batch liquid samples in a container.

Figure 10 Pressure feeder for liquid samples in a container. (Adapted from A. Lieberman, *Contamination Control and Cleanrooms: Problems, Engineering Solutions, and Applications*, Van Nostrand Reinhold, New York, 401, 1992.)

When measuring samples taken from a process or product stream, isokinetic sampling is encouraged, but is seldom required for particles smaller than 10 μm in diameter. Sample removal from a process or product line by a sidestream sample line should be at least 12 line diameters before or after a change in line orientation or size. A sidestream can be removed from the sampled main line and the entire sidestream passed through the sensing volume. The sidestream volumetric flow rate should be controlled so that the flow is equal to the flow at which the particle counter was calibrated. Flow rate through the sidestream line can be measured with an internal flowmeter, preferably a nonintrusive type.

Background Noise Pulse Rate. With no liquid flowing through the sensing volume, the electronic system is set to report data in the cumulative mode. The first size range is set to the manufacturer's level for the lowest size sensitivity of the instrument. Approximately 25 mL of clean liquid is added to a carefully cleaned sample container and the sensor and sample line are flushed with three 10-mL batches of clean liquid without collecting any data. The sample feeder is set to feed a sample of at least 20 mL to the sensing volume for particle measurement. The previous sample passage of three replicate samples is repeated and the particle count data recorded. The average count reported per milliliter of liquid is determined. This value will represent the noise count rate of the instrument. Noise counts should not be generated at a rate greater than 5% of the counting rate anticipated for the samples to be measured.

Particle Sizing Accuracy. Two procedures are available for determining particle sizing accuracy. Either monodisperse particles of verified sizes can be used to set the sizing response of the instrument or a suspension of polydisperse particles with a verified size distribution and concentration can be used for that purpose. The choice is based on the degree of similarity of either of these calibration particles to the particulate materials to be measured. When the monodisperse particles are chosen, the procedure for setting the particle counter response is essentially identical to the procedure used for the gasborne particle counter calibration. Use of monodisperse latex particles for sizing calibration is required to calibrate particle counters used for measurement of pharmaceutical and health care products, to verify potable water cleanliness, to measure particles with little absorption, and in areas where measurement of submicrometer particles is required. The polydisperse particles are used to calibrate instruments used for measurement of particle content of hydraulic fluids, fuels, and lubricants. The photomicrographs of Figure 11 illustrate the difference between the two calibration particle types. The monodisperse particles are transparent and identical in size and configuration. The polydisperse particles are irregular in configuration and do not all have the same optical properties, as noted by the differences in shade between different particles.

The cumulative particle concentration per milliliter of suspension can be calculated from data, similar to those shown in Table 1. This table provides an example of the cumulative concentration of polydisperse particles as threshold size increases. Batch-to-batch data will be within the limits given in Table 1 for materials fitting within the specification for ISO ultrafine test dust (UFTD). Similar tabulated information is available for ISO fine, ISO medium, and ISO coarse test dusts to permit calibration over a wider size range.

There is one problem found when using the polydisperse calibration particles that is present with all the ISO test dusts. This problem is caused by the wide range of particle concentrations from the smallest to the largest particles in the batch. The result is that statistically valid particle count data cannot be obtained for the large particle sizes unless the suspension concentration is so high

Figure 11 (a) Monodisperse 10-μm polystyrene latex particles and (b) ISO fine test dust. The scale in both photomicrographs defines 2.2 μm. (Reproduced by permission of Duke Scientific Corp.)

Table 1 ISO UFTD particle size distribution, number of particles per microgram

Particle size (μm)	Cumulative concentration, ISO UFTD particles ≥ stated size must be between:
1	70 000 and 100 000
2	19 000 and 29 000
3	8600 and 13 000
4	5400 and 8100
5	3300 and 4500
6	1600 and 2500
7	660 and 1400
8	280 and 760
9	120 and 410
10	58 and 220
11	28 and 120
12	14 and 63
13	7.4 and 34
14	4.1 and 19
15	2.3 and 11

that the small particle concentration exceeds the maximum concentration capability of the particle counter. In this situation, calibration for large particle sizing takes advantage of the situation shown in Figure 5. Monodisperse calibration particles can be obtained in the ''large'' sizes where there are insufficient large particles in the polydisperse calibration suspension for statistically valid data. As seen in Figure 5, the refractive index does not affect the extinction coefficient. Therefore, use of the large monodisperse particles permits definition of the counter response in the sizes where the polydisperse suspension will not provide adequate data.

Particle Sizing Resolution. Particle sizing resolution is determined using monodisperse calibration particles at least twice as large as the lower sizing limit of the instrument. The increase in relative standard deviation for the reported particle size range for the monodisperse particles selected for this measurement should be determined. The same procedures used to determine sizing resolution for the airborne particle counter could be used here. Most particle counter specifications for sizing resolution state that the counter will not increase the relative standard deviation shown for the monodisperse calibration particles by more than 10%. If the data fit that level, this requirement is met.

Particle Counting Accuracy. A batch of monodisperse particles with diameter in the size range from 5 μm to 25 μm is selected. These limits are chosen to permit ease of viewing at the small size end of the range and to minimize problems of loss due to deposition, settling, or inadequate dispersion at the large particle size end of the range. A suspension of these particles is prepared and the total particle concentration in the suspension is determined. Three aliquot samples of the suspension are passed through the sensing volume of the particle counter being validated and through the sensing volume of a particle counter that has been confirmed to have 100% counting efficiency for the particles in the size range selected. Both counter sensing volumes should be connected in series with a short length of tubing. The counter being calibrated should report count data equivalent to the data reported by the verified counter.

Particle Concentration Limit. The maximum concentration that can be accurately measured is limited by the accepted coincidence error. This error is due to the probability that more than one particle is present within the sensing volume at any time. The procedure for determining the maximum concentration limit is to pass a series of diluted suspensions with known dilution ratios through the sensing volume and to note the point at which the reported concentration ratio from one suspension to the previous suspension in the series is equivalent to the dilution ratio for the two suspensions. Since many liquidborne particle counters are used for measurement of a wide range of particle sizes, polydisperse particle suspensions are used to determine the maximum recommended particle concentration for liquidborne OPCs.

8 PERFORMANCE CAPABILITIES OF PRESENT DAY OPTICAL PARTICLE COUNTERS AND POSSIBLE FUTURE DEVELOPMENTS

8.1 Particle Size Capabilities

The smallest discrete particle that can be reliably counted and sized by commercially available OPCs for either gasborne or liquidborne particles is 0.05 μm in diameter. This capability applies for liquidborne particle counters used for measurement of particles in liquids that can be handled in glass and stainless steel with no attack on the counter materials of construction. If liquids as aggressive as hydrofluoric acid are to be used, then the sensitivity is decreased so that the smallest particle reliably counted and sized in those liquids is 0.075 μm in diameter. It is anticipated that the minimum size sensitivity will be 0.03 μm for gasborne particle counters and for liquidborne particle counters handling inert liquids before the end of the year 2000. No estimate of the maximum sensitivity for these instruments can be made at this time, but the need to define particles as small as possible is a continuing demand on the development capabilities of OPC producers. As part of the sizing capability of OPCs, particle sizing resolution is also a performance parameter

of concern. As an example, the calibration procedures and specifications in the section 6 documents for health care product testing specify that sizing resolution shall be no worse than 10%, particularly for liquidborne particle counters used to characterize large-volume and small-volume injectable liquids. Better control of illumination uniformity from laser light sources is expected to improve sizing resolution for both gasborne and liquidborne particle counters to the point where resolution worse than 5% will not be accepted in the health care product area after the year 2001. The other parameter connected with particle size measurement is the dynamic range of the instrument. This parameter defines the range of particle sizes that can be measured accurately. Particle counters with a 100 : 1 dynamic range are available. For application to measurement of particles in areas where a wide range of materials are used, a dynamic range of 1000 : 1 would be required. Use of advanced electronic systems with built-in autoranging amplifier gain control systems will permit operation of the particle counter over larger dynamic ranges. The capability of reporting particle size distribution in a very large number of size ranges has been seen in some listings of particle counter performance specifications. The capability to report accurate size data in more than 16 size ranges requires particle sizing resolution of 5% or better.

8.2 Particle Concentration Capability

In making measurements to characterize the particle content of fluids, the need for statistically valid data imposes a requirement to count sufficient particles to define particle content with a specified confidence limit (often 95%) as rapidly as possible. For gasborne OPCs, the capability of present day counters is adequate for most applications. Counters with gas flow rates of $47\,cm^3\,s^{-1}$ or $470\,cm^3\,s^{-1}$ can normally handle particle concentrations of $35\,cm^{-3}$ or $3.5\,cm^{-3}$. In situations where the particle concentration to be defined is beyond the capability of the counter, gas dilution can be used to decrease the measured concentration to the capability of the particle counter in use. The dilution system can be selected for a dilution ratio that will permit the true sample concentration to be defined correctly. For consistent measurement mainly of high concentrations of gasborne particles, as may be expected for many atmospheric research studies, optical gasborne particle counters with very small sensing volumes can be used to measure particle concentrations up to $2 \times 10^4\,cm^{-3}$. For valid measurements at such concentrations, sample gas flow rates may be in the range of $0.1\,cm^3\,s^{-1}$.

Particle concentrations in liquids are frequently higher than those in gases. Thus, the sample flow rates used in liquidborne OPCs are usually lower than those used for gasborne counters. For measurement of particle concentrations up to $10^4\,mL^{-3}$, a liquid sample flow rate of $0.0017\,mL\,min^{-1}$ is used. For measurement of particle concentrations up to approximately $35\,mL^{-3}$, a liquid flow rate of $1.67\,mL\,min^{-1}$ is used. Under these conditions, the liquids of concern can be characterized with present day instrument capability. As requirements for product quality increase, it is anticipated that there will be only a minor requirement for instruments that can measure particles in concentrations higher than present day instruments can handle. One example of the area where such a need may exist is in characterization of high-efficiency filter systems where the challenge concentration must be high enough so that even the few particles that penetrate the filter will be sufficient to permit reliable definition of the filter efficiency for particles at the most penetrating particle size.

8.3 Optical Particle Counter Configuration and Size

The particle counter described by Fisher et al.[1] was built in 1954. It operated with an electronic system using vacuum tubes. The optical system used an incandescent filament lamp for illumination and a photomultiplier tube photodetector. The electronic system required two 1.8-m relay racks to contain those components. The optical system was a right angle scattering system using lenses to direct the illumination beam and to collect the scattered light. The optical system weight was approximately 67 kg and the electronic system weight was approximately 135 kg. The instrument counted and sized particles from 1 to 64 μm in 12 size ranges. The sample air flow rate was $47\,mL\,s^{-1}$ and the maximum concentration capability was 1.1 particle cm^{-3}. This instrument can be compared with a recently described high-sensitivity airborne particle counter.[12] The counter is capable of counting and sizing airborne particles $\geq 0.05\,\mu m$ in an air sample flow of $47\,mL\,s^{-1}$. The illumination source is a solid-state laser. Parallel processor array detection permits background noise from air molecule scattering to be minimized. Light scattering over a scattering angle of $90° \pm 45°$ is collected by Mangin mirrors (concave spherical mirrors that collect and focus light to the photodetector) and focused upon a solid-state photodetector array. This instrument has a dynamic range capability of 100 : 1, allowing measurement of particles from 0.05 to 5 μm in diameter with sizing resolution of 3%. Data are reported in eight size ranges in either tabular or graphical format. The maximum recommended particle concentration is $35\,cm^{-3}$. Instrument operating parameters and data processing are controlled by an internal microprocessor. The entire instrument is in a package with dimensions of 100 cm width, 175 cm depth, and 25 cm height. The weight is approximately 15 kg. Data from this instrument can be

printed on a small on-board printer, stored internally on diskette, or transmitted to a central computer.

The comparison between the counter described in 1955 and that described in 1988 indicates that developments in performance have continued and that improvements in the performance of these instruments have not stopped. It is anticipated that future development will result in sensitivity to smaller particles – at a relatively slow development rate – and better sizing resolution as illumination source uniformity improves. The detection capability will also be modified. By adding a photodetector capability at wavelengths other than that of the illumination source, identification of some particle chemical composition becomes possible. This feature is being developed to identify microbiological materials and will probably be extended to other materials as new lasers are developed with more emission wavelengths. This type of activity is mainly aimed at identification of material type (organic, inorganic, etc.). Laboratory instrumentation for detailed analysis of single micrometer size particles has been used for several years.[13] Aerosol particles were collected and were analyzed by electron probe X-ray microanalysis and laser microprobe mass analysis. These techniques were used for trace element measurements by particle-induced X-ray emission. As more powerful lasers become available, the possibility of real-time analysis of individual airborne particles drawn into an instrument and analyzed in situ becomes a distinct possibility. This will permit identification of sources when ambient air pollutants are measured, as well as controlling product uniformity for powders.

Other areas where changes can be expected are in the counter size, functions, cost, and maintenance requirements. Better portability of OPCs has been a need expressed by users where modifications in process or product require measurements at different locations on an unscheduled basis as required by changing process conditions. This is a particular need when personnel must have a particle counter at a location where access is difficult or adequate space is a problem. The need for portable OPCs has resulted in development of battery-operated counters that are handheld, weigh 1 kg or so, and are capable of counting and sizing particles $\geq 0.3\,\mu m$ in sample air flows of $47\,cm^3\,s^{-1}$. These counters can report data in two to six particle size ranges. The electronic system can include a data storage capability of several hundred measurements with records of sample point location, time of measurement, and particle concentration data in the specified size ranges. Internal components are easily and quickly removable and replaceable with calibrated components that are kept in stock and can be inserted by any technician with minimum training required. A routine calibration procedure can be carried out in a central metrology facility for these components. The procedure is compatible with the procedures in the documents shown in section 6. Both the instrument producers and users should keep current issues of the calibration procedure documents at hand and be aware of any changes that have been made in the procedures. A ''calibration certificate'' should be prepared and filed with the cleanroom records for each instrument. The counter calibration status should be indicated on a tag attached to its case.

Particle measurement is the primary function of OPCs. However, particle morphology is also of interest in many areas. As digital photography technology continues to advance, the use of an image analyzer to report magnified image data on a two-dimensional pixel array can provide two-dimensional image information. This would be similar to the data based on photomicrograph images. By adding a second image detector to observe the particle in a direction orthogonal to that used by the first detector, a three-dimensional image may also be definable.

8.4 Capital and Operating Costs

Actual prices for OPCs will not be given here. During the interval between preparation of this article and distribution of the printed material, both technical developments and production costs will change pricing of OPCs. However, certain considerations will still affect the prices. An increased quantity of data to be reported will increase costs. Counters with the capability to measure very small particles will be more expensive than those with sensitivity for particles larger than 0.3–0.5 μm. A further increase in price by a factor of two to five can be expected when measurement of particles smaller than 0.1 μm is required.

Liquidborne particle counters require sample feeders that may increase system cost by a factor of twice the particle counter cost, depending upon requirements imposed by the nature of the liquid and the sample handling requirements for that liquid. Hazardous liquids of all types require costly containment and safety systems. Even with this significant capital cost, the savings in labor and facility costs when individual samples must be handled, measured and data processed for each one may result in savings that could pay for the sample feeder in a reasonable time. Uniformity of sample handling operations can also result in data that are more reliable than data produced by manual sample handling procedures.

Eventually the OPC will become a commodity product, similar to the way in which a voltmeter or oscilloscope is. For organizations large enough to incorporate a metrology facility, repairs and calibration can be carried out in that facility. For smaller organizations, express

shipments to and from a central repair and calibration facility may become the maintenance procedure for these and many other instruments. If this situation occurs, then capital costs for the OPC will drop to some extent and the labor costs for service will decrease even more.

Photon correlation spectroscopy (PCS) has become a powerful light-scattering technique for studying the properties of suspensions and solutions of colloids, macromolecules and polymers, that is absolute, non-invasive and non-destructive. This text explains the principles of the technique and describes the required instrumentation. It also discusses new developments in instrumentation, which may substantially impact on future applications of this technique. Proper sample preparation is of major importance for the accuracy and precision of the mean size and size distribution results and thus one section is dedicated to sample handling.

1 INTRODUCTION

The acronym PCS is only one of several different names that have been used historically for this technique. The first name given to the technique was quasi-elastic light scattering (QELS) because, when photons are scattered by mobile particles, the process is quasi-elastic. QELS measurements yield information on the *dynamics* of the scatterer, which gave rise to the acronym DLS (dynamic light scattering). Another name, IFS (intensity fluctuation spectroscopy) was used by several authors in the past. Throughout this text the acronym DLS will be employed because its use has become more prevalent and presents a logical juxtaposition to SLS (static light scattering). Application of the DLS technique to particle sizing and commercial availability occurred only about seven years after the first size measurements[1] were made in 1972 merely to check the alignment of a multi-angle research light scattering system. Slowly, through the 1970s, DLS gained wide acceptance among experts in light scattering. This text is not meant to be exhaustive and emphasizes the application of DLS for particle sizing which relates to the *translational* motion (diffusion) of particles in liquids. However, DLS, by its nature, is not limited to this mode: any *time variable* parameter, such as the rotation or vibration of scattering centers, or fluctuations in the refractive index, entropy, thermal diffusivity etc. can be measured. The reader is referred to the extensive literature that exists on these subjects.

2 HISTORY

All materials scatter and absorb light and since the first light-scattering experiments described by Tyndall,[2] SLS experienced major developments in the first half of the 19th century and is well described in the publications by Kerker.[3] DLS theory is built upon the earlier foundation of classical light-scattering theory, which is usually dated

by Rayleigh's papers[4] in 1871 on the scattering from a single particle small compared to the wavelength of light. Scattering from larger particles was added later and is known as Mie scattering, which gives the complete solution for spherical particles of any size. As early as 1908 the temporal fluctuations about the average scattered light intensity were identified with the motion of the particles and their diffusion coefficients. Einstein[5] had already published the relationship between diffusion and size, so in principle the way was open for the birth of a new particle sizing technique. The fundamentals have been written about very often and these references should be consulted for a more complete treatment.[6–26] The history of experimental DLS begins with the advent of the laser. In the early 1960s Pecora[27] pioneered a new kind of light scattering: *time dependent* light scattering. He showed that, by analyzing the frequency distribution of the intensity fluctuations of light scattered from suspensions of macromolecules, information can be obtained about the translational and rotational diffusion coefficients of the macromolecules. Initially DLS was used to measure the diffusion coefficient of macromolecules, from which a hydrodynamic size was calculated. A few industrial users tried this technique for submicron particle sizing, mostly to replace transmission electron microscope (TEM) measurements in quality control (QC) applications. During the second half of the 1970s improvement of digital correlators and the introduction of several algorithms for analyzing decay time distributions were seen. Measurements that had taken months to set up and hours to make, were now reduced to minutes. Bertero et al.[28,29] published a fundamental paper in 1984 that derived the limiting conditions for the resolution of the "noisy" sum of an unknown number of exponentials based on information theory. The advent of highly efficient nonlinearly spaced correlators ushered in a steep ascent of the utility of DLS particle sizing in the mid-1980s, and the emerging fast computers speeded up data handling. Unfortunately, the pretty pictures and rapidly achieved size distribution results often mask the real underlying limitations that are imposed by the physics of the technique.

3 PRINCIPLES OF DYNAMIC LIGHT SCATTERING

3.1 Origin of Intensity Fluctuations

Colloidal sized particles in a liquid undergo random ("Brownian") motion owing to multiple collisions with the thermally driven molecules of the liquid. The scattered light intensity from these diffusing particles will fluctuate in time, thus carrying information about the diffusion

Figure 1 The basics of DLS.

coefficient of the particles. Cummins, Knable and Yeh[30] demonstrated a method to determine the spectrum of light scattered from a dilute suspension of polystyrene spheres by employing novel optical techniques. Following is a description of the basic physics of the DLS technique and of the instrumentation employed in these measurements. The approach used is not intended to be exhaustive; for more details, the literature presented at the end of this article should be consulted. The NATO proceedings edited by Cummins and Pike[7,8] are particularly valuable. The volume edited by Chu[9] conveniently collects many of the major papers together. The article by Ford[25] provides an excellent introduction to many of the practical aspects of the technique and the book by Wyn Brown[26] contains many valuable contributions to various data transformation methods. Equation (1) describes the time averaged scattered intensity $\langle I(q)\rangle$ in terms of particle parameters (also see Figure 1)

$$\langle I(q)\rangle = KNM^2P(\Theta)B(c) \tag{1}$$

$$q = \frac{4\pi n}{\lambda_0}\sin\left(\frac{\Theta}{2}\right. \tag{2}$$

where q is the magnitude of the scattering vector, Θ is the scattering angle, λ_0 is the wavelength of the laser in vacuo and n is the refractive index of the suspending liquid; K is an optical constant, N is the number of scattering particles, M is the mass of a particle, $P(\Theta)$ is the particle form factor, and $B(c)$ is the concentration factor. The terms M^2 and $P(\Theta)$ are of particular importance for the determination of size distributions. The central concept in DLS is as follows: the diffusion of the scatterers (Brownian motion) causes the phases of the fields scattered from each of them to change with time so that the *total* scattered intensity will fluctuate with time owing to constructive and destructive interference. The source of the intensity fluctuations can be understood with reference to Figure 1. A laser beam of wavelength λ is incident on two identical particles. Light scattered by the particles is received by a photo multiplier tube (PMT) and it can be readily seen that the pathlength

difference between the scattered waves is $d_p \sin(\Theta)$. When this pathlength difference is equal to an integer multiple of wavelengths $d_p \sin(\Theta) = m\lambda$, the wavelets will arrive at the detector *in phase* (constructive interference), i.e. the total intensity will be twice that from a single particle. When the pathlength difference is a half integer multiple of wavelengths $d_p \sin(\Theta) = \lambda/2, 3\lambda/2, 5\lambda/2, \ldots$, then the two wavelets will be exactly *out of phase* (destructive interference), i.e. the resulting intensity will be zero. The relative positions and orientations of the particles undergo Gaussian random changes in time (Brownian motion). The result is a total intensity which fluctuates in time from zero to double the single particle scattered intensity. In a real experiment there are perhaps $\sim 10^8$ particles in the scattering volume, and the total intensity is the result from the interference between the scattered fields from all of these. As a consequence, the intensity $I(t, q)$, as seen by the detector, will be a randomly fluctuating signal as shown. Its well-defined mean value, $\langle I(q) \rangle$, is the quantity measured in a SLS experiment. The intensity fluctuations are not readily observed because they occur on a rapid timescale (10^{-6}–10^{-3} s) and because they take place only at a point (Ford[31]). The first condition necessitates a high-speed detection and recording system. The second condition is of fundamental importance in DLS measurements because it determines the limiting properties of the optical system. When the light scattered from a suspension of colloidal particles undergoing Brownian motion is projected onto a screen or wall, a granular pattern (''speckles'', bright and dark patches) is observed. The integral intensity appears constant. However, the intensity of each individual speckle changes randomly in time from very dark to very bright. The intensity of adjacent spots also fluctuates, but independently. Thus the largest spread in intensity (the fluctuations) will be obtained by looking at exactly only one spot. As the number of spots observed increases, the magnitude of the fractional intensity *fluctuations* will decrease, because the spots' intensities fluctuate independently and the high probability of one spot's intensity increasing and another's decreasing yield small integral fluctuations, even though the *total time averaged* intensity increases by observing several speckles simultaneously. The intensity fluctuations will be in phase, or coherent, if the light is detected over one ''coherence area'' (one speckle) the size of the coherence area. For the configuration shown in Figure 1, where a scattering volume of diameter d_p is a distance R away from a detector, the size of the coherence area A_{coh}[15] is given by Equation (3):

$$A_{coh} = \frac{4\lambda^2 R^2}{\pi d_p^2} \tag{3}$$

The area of the detector is given by Equation (4)

$$A_{det} = \frac{\pi d_{det}^2}{4} \tag{4}$$

and if this is set equal to A_{coh}, the size of the detector that is sufficient to see only one coherence area may be calculated. For a typical arrangement with $\lambda = 475$ nm (HeNe laser wavelength in water), $R = 15$ cm and d_p (the diameter of the scattering region) $= 0.2$ mm, the diameter of the detector d_{det} will be ~ 0.9 mm for one coherence area, i.e. a detector aperture of ~ 0.9 mm is required to see one spot and achieve the maximum signal-to-noise ratio (S/N). Since there is no advantage for most experimental conditions in collecting more than one coherence area, it is important to have the maximum intensity scattered into a small area. This is achieved by tightly focusing the incident beam to decrease d_p and increase the size of the coherence area (Equation 3).

3.2 Detection Limits and Ranges

Several experimental conditions must be met for the applicability of the relevant physics for SLS and DLS techniques in general, and particle sizing in particular (also see Table 1 in section 4):

3.2.1 The Optical Mixing Mode

Any measurement must use exclusively one of the following three optical mixing modes:

Table 1 Summary of measurement problems

Condition	Cause	Effect
Multiple scattering present	Concentration too high	Measured sizes *too low*
Stray light present	Light reflections	Measured sizes *too large*
Dust present	Sample preparation	Incorrect size distribution
Duration too short	Operator impatience	Unrepeatable results
Ergodicity not assured	Nature of the sample	Unrepeatable results
Size range exceeded	Operator ignorance	Unrepeatable results
Sample not stationary	Aggregation, sedimentation	Unrepeatable, averaged results
Sample preparation	Impatience or ignorance	Incorrect or unrepeatable results

- Self beating: the scattered light mixes on the photo multiplier cathode with itself.
- Homodyning: the scattered light mixes with a strong signal from the same laser. This signal, a *local oscillator*, must have the *same* frequency, must be at least an order of magnitude higher than the scattered light, and must be in phase with it. If the auto correlation function (ACF) contains a mix of self beating and homodyning, the calculated sizes are invalid. Unfortunately there is no easy way to recognize this problem when it is present. Only one commercially available instrument employs the *homodyning* mode for particle sizing.[32]
- Heterodyning: the scattered light mixes with a strong signal of a *different* frequency (a local oscillator), which is generated either by frequency shifting the same laser or by using a laser beam with a different frequency.

It should be noted that in the literature the terms self-beating and homodyning are frequently used interchangeably and homodyning is confused with *heterodyning*. Here these terms are used according to their true definitions: DLS-based particle sizing applications operate almost exclusively in the self-beating mode, *homodyning* is used rarely and *heterodyning* is not employed at all. However, DLS Doppler (velocimetry) experiments are conducted almost exclusively in the heterodyne mode.

3.2.2 Concentration

The concentration must be sufficiently low so that in Equation (1) $B(c) = 1$ and *multiple scattering* (see below) is avoided, but also must be sufficiently high to prevent signal distortions due to number fluctuations. The number of the particles in the scattering region must always be sufficiently high to maintain a constant $\langle I(q)\rangle$ (Equation 1).

3.2.3 Multiple Scattering

Unless the concentration is vanishingly small, any scattered photon has a non-zero probability to be scattered again while traveling through the sample. The ACF of such multiple scattered light decays faster, yielding an apparent smaller particle size. Thus the sample concentration must be kept sufficiently low and/or the optical path must be sufficiently short to avoid multiple scattering.

3.2.4 Ergodicity

All particles must have an equal opportunity to be measured. This condition is sometimes difficult to meet if the diffusion coefficient of the scatterers is very low, see Pusey.[19,33]

3.2.5 Stationary Process

Scattering conditions must not change during the measurement.

3.2.6 Stray Light

Stray light must be avoided to prevent inadvertent homodyning (see section 3.2.1) and commonly determines the low limit of the angular measuring range.

3.2.7 Sample Preparation

The term M^2 in Equation (1) predicts the scattered intensity to be $\propto d^6$. Consequently a few large particles (commonly called ''dust''), will overwhelm the desired signal (see section 4).

3.2.8 Size Range

The DLS technique is commonly employed in the range of 0.002 to 2 microns. The low limit is usually determined by the available laser power. The high limit results from sedimentation and number fluctuations due to the low number of large particles that fit into the small scattering volume.

3.2.9 Measurement Duration

The typical range is from 1 to 10 minutes, depending on $\langle I(q)\rangle$.

3.3 Time Domain Data Acquisition of a Random Signal (Correlation)

To see how the signal $\langle I(q)\rangle$ changes with time it is convenient to compute its ACF. The *intensity* ACF is described by Equation (5):

$$G^{(2)}(t_d) = \frac{1}{N}\sum_{i=1}^{N} I(t_i)I(t_i - t_d) = \langle I(t)I(t - t_d)\rangle \quad (5)$$

The angle brackets indicate a time average, N is the number of samples and t_d is the time delay between the samples. Experimentally, $G^{(2)}(t_d)$ is determined by recording $I(t)$ at time intervals much shorter than the timescale of typical fluctuations and accumulating the products of the intensities as a function of (t_d). For a dilute suspension of monodisperse spheres (e.g. latex particles), $G^{(2)}(t_d)$ can be written as Equation (6):

$$G^{(2)}(t_d) = B + f \times e^{-2\Gamma t_d} \quad (6)$$

where $B = \langle I \rangle^2$ (Figure 1) is the baseline, f is an instrumental constant and 2Γ is the reciprocal of the decay time τ. $G^{(2)}(t_d)$ is normalized by dividing Equation (6) into the base B, yielding in Equation (7) the normalized intensity ACF $g^{(2)}(t_d)$. For Gaussian statistics Glauber[34] derived Equation (7) via the Siegert relation[35]

$$g^{(2)}(t_d) = 1 + a[g^{(1)}(t_d)]^2 \tag{7}$$

relating the electric field ACF $g^{(1)}(t_d)$ to the measured intensity ACF $g^{(2)}(t_d)$, and a is an instrumental constant that is now between 0 and 1. It should be noted that any photoelectric detector is sensitive to the intensity of light, which is the square of the field amplitude. The normalized electric field ACF $g^{(1)}(t_d)$ may be written as Equations (8) and (9):

$$g^{(1)}(t_d) = G_0 e^{-\frac{t_d}{\tau}} \tag{8}$$

$$\Gamma = \tfrac{1}{\tau} = D_T q^2 \tag{9}$$

where $\tau = 1/\Gamma$ is the decay constant and D_T is the translational diffusion coefficient of the spheres, and G_0 is the intercept of the exponential function, $g^{(1)}(t_d = 0)$. In the case of measurements on dilute monodisperse spheres, the intensity ACF will be a simple exponential function as shown in Figure 2. The significant parameter in Equation (8) is τ, which is invariant to the scattered intensity $\langle I(q) \rangle$. Thus, for DLS-based measurements, the absolute intensity is of secondary importance, as long as it is sufficiently large to complete the experiment within the lifetime of the operator or the stability of the sample, whichever comes first. Measurements in the frequency domain yield the same information; in Equation (10) the power spectral density $S(w)$ is the Fourier transform of $g^{(1)}(t_d)$ and has the shape of a Lorentzian.

Figure 2 Semi-log plot of a single mode ACF.

$$S(w) = \langle I(t) \rangle \frac{(2\Gamma)^2}{w^2 + (2\Gamma)^2} \tag{10}$$

The relationship between Γ and τ is defined in Equation (9), from which the particle diffusion coefficient D_T can be calculated. Finally in Equation (11), for spheres, D_T is related directly to their hydrodynamic radius r_h by the Stokes–Einstein relationship

$$D_T = \frac{k_B T}{6\pi\eta(T) r_h} = \frac{k_B T}{3\pi\eta(T) d_h} \tag{11}$$

Here k_B is the Boltzmann constant, T is the absolute temperature (Kelvin) and $\eta(T)$ is the viscosity of the suspending liquid (the viscosity is strongly temperature-dependent, requiring a constant temperature throughout a measurement); r_h and d_h are the hydrodynamic radius and diameter respectively; these values are almost always larger than the dry particle diameter owing to the ''double layer'' that forms around charged particle surfaces. The counter-ions around the particle form a diffuse region which moves with the particle. An important parameter for colloidal stability, the ''zeta potential'', is defined at approximately the location of the shear plane (the outer ''edge'' of the diffuse double layer).

3.4 Data Reduction and Transformation

The simplest case involves a single exponential decay for a monodisperse sample as shown in Figure 2 (owing to the logarithmic time axis, the ACF is 'S' shaped). After dividing the correlation coefficients into the baseline and subtracting 1, the remaining part, $G_0 e^{-\Gamma t}$, is fit using a least-squares technique. The value of G_0 typically varies from 0.1 to 0.9 depending on the optical configuration. G_0 is a maximum when the coherence criterion is met. The particle diameter is calculated from D_T in Equation (11). Typical results on latex spheres show the technique is as reliable as an electron microscope on monodisperse samples or latex spheres. The size calculated from Equation (11) is a hydrodynamic diameter.

3.4.1 Monodisperse Distribution

The results for monodisperse samples can be compared directly with other techniques since there is only one ''average'' diameter. For nonspherical particles either the results can be interpreted in terms of an equivalent sphere diameter equal to the Stokes–Einstein hydrodynamic diameter, or the diffusion coefficient can be interpreted in terms of ellipsoids of revolution.[36] This requires either independent knowledge of one dimension or their ratio,

Figure 3 Bimodal distribution of an emulsion.

or angular measurements from which, in favorable cases, both dimensions can be calculated.[37]

3.4.2 Polydisperse Distribution

The interpretation of data from polydisperse samples (Figure 3) is considerably more difficult. Since the technique does not count single particles, size distribution information must be obtained from the deconvolution of the sum over all the single exponentials contributing to the measured ACF. The general deconvolution of a sum of single exponentials is difficult. The problem may be summarized by Equations (12) and (13) which define the normalized field ACF $g^{(1)}(t_d)$ as the sum of m particle sizes, each of which contributes $G(\Gamma_i)$ for the i-th size class.

$$\begin{aligned} g^{(1)}(t_d) &= G(\Gamma_1)\, e^{(-\Gamma_1 t_d)} + G(\Gamma_2)\, e^{(-\Gamma_2 t_d)} \\ &\quad + G(\Gamma_3)\, e^{(-\Gamma_3 t_d)} + \cdots \\ &= \sum_{i=1}^{m} G(\Gamma_i)\, e^{(-\Gamma_i t_d)} \end{aligned} \tag{12}$$

Here Γ_i is the value as defined in Equation (9). For the limit of $\Gamma_{i+1} - \Gamma_i = \Delta\Gamma = 0$, $g^{(1)}(t_d)$ is defined in Equation (13) by integrating over the entire range of particle sizes

$$g^{(1)}(t_d) = \int_{\Gamma_{min}}^{\Gamma_{max}} G(\Gamma)\, e^{-\Gamma t_d}\, d\Gamma \tag{13}$$

where $G(\Gamma)$ represents the distribution of line widths due to the distribution of particle sizes. Γ_{min} and Γ_{max} define the range of line width; in principle, $\Gamma_{min} = 0$ and $\Gamma_{max} = \infty$. It is easy to calculate $g^{(1)}(t_d)$ from a known size distribution $G(\Gamma)$, but exceedingly difficult to perform the inverse transformation to extract $G(\Gamma)$ from $g^{(1)}(t_d)$. Equation (13) belongs to a class of linear transformations (Laplace) that are known to be ill-conditioned. In the presence of any noise, many different solutions for the functional form of $G(\Gamma)$ are possible. A repeat measurement on the same sample will yield a slightly different $g^{(1)}(t_d)$ with a slightly different noise contribution, resulting in a different $G(\Gamma)$ and hence in a different size distribution $G(d)$. This behavior can render the results of a DLS instrument apparently "not repeatable". For these fundamental reasons of physics DLS will not become a high-resolution technique for particle sizing. Numerical solutions of Equation (13) were attempted by Chu and Gulari,[38] McWhirter and Pike,[39] McWhirter[40] and Ostrowsky and Pike[41] have demonstrated that $G(\Gamma)$ can be calculated at exponentially spaced delay times. The method, called *exponential sampling* introduces ϖ_0 as a parameter that limits the resolution of $G(\Gamma)$ for a given noise level in Equation (14).

$$\Gamma_{i+1} = \Gamma_i\, e^{\frac{\pi}{\varpi_0}} \tag{14}$$

Here ϖ_0 is the largest value for a fixed noise content of $g^{(1)}$ and therefore defines the best possible resolution for Γ_i and Γ_{i+1}. Example: if $\varpi_0 = 3.14$, $\Gamma_{i+1}/\Gamma_i = 2.71$; if Γ_{i+1} corresponds to a size of, e.g. 500 nm, the next neighboring peak cannot be closer than 184 nm (500/2.71) or 1050 nm (500*2.71). If the inversion routine asks for a higher resolution than can be supported by the ACF, the Gamma distributions will exhibit more and more artifacts such as additional maxima and negative values for $G(\Gamma)$. The practical limit for the ratio Γ_{i+1}/Γ_i is 2. It is important to note, that this resolution cannot be exceeded by any transformation routine without imposing additional, a priori imposed, constraints. The most commonly applied constraints are non-negativity (only zero or positive $G(\Gamma)$ are allowed), range limitations and force fits to specific distribution models (log-normal, bimodal). Provencher[42,43] has developed an effective inversion software package, CONTIN, which is a generalized Inverse Laplace Transform with constraints and parsimony. CONTIN contains a non-negative least square routine (NNLS), that may be used effectively as a fast executing stand-alone program to obtain rapid size distributions in real time during data acquisition.[44] Several other inversion programs are in use by practitioners, e.g. "Maximum entropy",[45] "REPES"[46] and "single value decomposition".[47,48] H. Ruf[49] investigated the errors that are introduced into the inversion process owing to normalization errors. Aside from the noise content of the ACF, baseline errors contribute a significant amount of ambiguities to any of the transformation routines and repeated, iterative, normalizations of the ACF can improve the stability of the results. The above approaches show that only a few parameters of the distribution can be calculated from typical experimental measurements of the correlation function. Present work on these advanced techniques is focusing on the separation of only two peaks

in a size distribution, the size ratio of which is at least 2 : 1. Thus DLS measurements must be considered as relatively insensitive to the particular size distribution and only a few moments of the distribution can be obtained, except for monodisperse samples, for which the technique works extremely well.

3.4.3 Cumulants

The most widely used and simplest data analysis technique to apply is the *method of cumulants*.[50,51] The method proceeds by expanding Equation (13) about an average line width $\langle\Gamma\rangle$, to give Equation (15):

$$\ln[a_0 g^{(1)}(t_d)] = a_0 - \langle\Gamma\rangle t_d + \frac{\mu_2}{2}t_d^2 - \frac{\mu_3}{6}t_d^3 + -\cdots \quad (15)$$

where a_0 is a constant and $\langle\Gamma\rangle$, μ_2, etc. are moments of the line width distribution $G(\Gamma)$. In practice only the first two moments are obtained with certainty, and care must be taken to limit the range of t_d such that higher order terms are negligible. Before the advent of non-linearly spaced correlator channels this used to be difficult for broad distributions. This technique has the advantage that no assumption about the form of the distribution is necessary, and, under the correct experimental conditions described earlier, the moments are well defined and useful parameters. It has been shown by Brown, Pusey and Dietz[50] that (Equation 16):

$$\langle\Gamma\rangle = \langle D_T\rangle q^2 \quad (16)$$

where $\langle D_T\rangle$ is given by Equation (17),

$$\langle D_T\rangle = \frac{\sum N_i M_i^2 P_i(\Theta) D_i}{\sum N_i M_i^2 P_i(\Theta)} \quad (17)$$

NM^2P is the time-averaged intensity weighting factor (Equation 1) for the contribution of D in the i-th size class. The sum is over all the particles contributing to the scattering, and it has been assumed that the measurements have been made or will be extrapolated zero concentration. If not, the interparticle interference term $B(c)$ must be included in Equation (17). It has also been assumed that the optical constant K in Equation (1) is the same for all particles independent of size. K includes the refractive index increment (change of solution refractive index with particle concentration). So the assumption of a constant K means assuming a sample of homogeneous composition independent of size. For Rayleigh scatterers ($d \ll \lambda$) and for all particles where measurements have been extrapolated to zero angle, where $P(\theta) = 1$, and

$$\langle D\rangle = \langle D\rangle_z = \frac{\sum N_i M_i^2 D_i}{\sum N_i M_i^2} \quad (18)$$

Here $\langle D\rangle_z$ is the well-defined z-average diffusion coefficient (z-weighting means the next higher weighting after volume). Thus, for spheres, where $M^2 \propto d^6$, the average particle size obtained is (Equation 19),

$$\frac{1}{d_z} = \frac{\sum N_i d_i^5}{\sum N_i d_i^6} \quad (19)$$

Here d_z is the inverse, z-average diameter and N_i is the number of particles in the i-th size class. The second moment in the cumulant analysis, μ_2 in Equation (20) yields (after extrapolation to zero concentration and zero angle)

$$\mu_2 = \langle D_z^2\rangle - \langle D_z\rangle^2 \quad (20)$$

which is the *variance* of the z-average diffusion coefficient distribution. For spherical particles the first term can be related to the inverse square, z-average diameter, $\langle(1/d^2)_z\rangle$. This technique has the advantage that no assumption about the form of the distribution is necessary, and the moments are well defined and useful parameters. A convenient polydispersity index is defined as Q in Equation (21)

$$Q = \frac{\mu_2}{\langle\Gamma\rangle^2} = \frac{\langle D_z^2\rangle - \langle D_z\rangle^2}{\langle D_z\rangle^2} \quad (21)$$

where μ_2, $\langle\Gamma\rangle$ and $\langle D_z\rangle$ are defined in Equations (20), (16) and (17) respectively. For QC measurements the exact interpretation of data is not usually of primary importance. In this case, measurement at one angle, usually 90°, is sufficient to establish an apparent average size and apparent measure of the width of the size distribution. Monitoring changes in these two parameters may be all that is required. In many cases the distribution is known to be log-normal or reasonably close to one; Thomas[52] showed that in this case the two parameters μ_2 and $\langle\Gamma\rangle$ may be mathematically transformed to geometric standard deviation and mass mean diameter, the two parameters that define a log-normal function. Such transformations are not limited to log-normal functions but can be performed for any other two parameter distribution. It is important, however, not to forget that this function may or may not resemble the real particle size distribution, although it definitely will produce a "nice" looking display on the computer screen.

4 SAMPLE PREPARATION

4.1 Concentration

Concentration effects manifest themselves in two fundamentally different ways:

4.1.1 Multiple Scattering

Even if D_T is indeed independent of c, the ''particle size'' will be reported as too small, because the correlation is lost on a shorter timescale for multiple scattered photons. A comparatively new set of experiments has been successful in analyzing the dynamics of multiple scattered photons from concentrated samples (see section 9).

4.1.2 Particle–Particle Interaction

The apparent viscosity depends on particle–particle interaction. In sufficiently high concentrations where particles experience significant interactions, the calculated particle size is different from those obtained under infinite dilution conditions. There is a large amount of physics to be learned from such experiments, as long as the instrument is capable of eliminating multiple scattering effects, so that the true functional form of $D_T(c)$ can be obtained and the theories for particle–particle interaction can be investigated (see section 9).

4.2 Stability of Samples

The scattering environment must not change during the measurement. Sometimes this is difficult or impossible to accomplish owing to the presence of changing chemical and/or physical parameters in the sample (chemical reactions, aggregation, temperature). If those changes are the objects of investigation, the experiment duration must be kept sufficiently small compared to the characteristic times of the reactions. Under most operating conditions, however, an unstable sample is the result of inappropriate sample preparation. The following describes a general approach to solving the sample preparation problem as it relates to particle sizing.

4.2.1 Coagulation

Physics predicts (van de Waals forces) that, allowing for a sufficiently long time, any colloidal dispersion will coagulate, be it seconds, minutes or years. Thus the problem to be solved can be stated very simply: how long is stability required? For particle sizing typically 30 minutes are sufficient, but for a commercial product a long shelf life is imperative. It will exceed the scope of this text to dwell on any details, but fortunately even only superficial attention to some basic surface chemistry will result in meaningful particle size measurements. Under most operating conditions an unstable sample is the product of inappropriate sample preparation. The following describes a general approach to sample preparation as it relates to particle sizing.

4.2.2 Hydrophobic or Hydrophilic Sample Surfaces?

Sprinkling a few particles on the surface of the water will rapidly reveal their properties: hydrophilic particles will rapidly disperse in the water, hydrophobic types will stay on the surface. The former will generally merely require a stabilizing surfactant, whereas the latter often can be converted into a hydrophilic system by creating a paste of the particles and methyl alcohol.

4.2.3 Zeta Potential

The ''zeta potential'' of particles (a measurement of the electrostatic repulsion between particles) is a good, but certainly not the only, predictor of the stability of a suspension. Unless the sample is sterically stabilized, a low zeta potential increases the probability for aggregation within a short time; thus the determination of this parameter is very important. Frequently a simple change of the pH value is all that is required to achieve a stable suspension. Further information about electrophoretic mobility (zeta potential) and the stability of colloidal systems can be found in a book by Hunter.[53]

4.3 Dust in the Sample

The appropriate use of surfactants to avoid aggregation, filtering, centrifugation, ultrasonication, cleaning of sample cells and the use of deionized and filtered water are of utmost importance for any serious size measurement. Dust will not only cause huge intensity spikes and distort the raw data but can also introduce unintentional homodyning to the self-beating mode by actually creating a local oscillator. Nonaqueous (nonpolar) liquids do not attract ''dust'' as much and are easier to clean, but sample preparation is often more complicated. Filtering of all liquids, especially water, and thorough cleaning of all sample cells as well as pipets, syringes, etc. are always required. DLS instruments, by their nature, will collect at least the dark counts from a detector, always resulting in some nonzero ACF. The computer will happily calculate a ''result'', regardless of the quality of the signal, thereby creating insidious and serious problems if any of the above listed conditions is violated. Table 1 shows a compilation of the most common error sources in DLS particle size measurements.

5 INSTRUMENT PERFORMANCE

5.1 Efficiency of Data Acquisition

The ACF consists of many product terms which asymptotically converge to a steady function. The overall

optimization of the statistics begins with the efficient launching of the laser beam, the collection of the scattered photons by bulk or fiber optics and the quantum efficiency (QE) of the detector. All available photon pulses should be utilized by the optics and the electronics in order to achieve the best possible statistics in the least amount of time. Here the design of correlators that do not require any prescaling presents a significant advance in this technology. Modern correlators do not depend on raw computer speed for data collection, but in QC applications the ''throughput'', which includes data reduction, display, storage and possible statistical process control (SPC) depends on the performance of the attached data processor.

5.2 Result Verification

DLS results are sometimes not easy to interpret since there always will be some result displayed. Several conditions can be stipulated for the correctness of the results:

- *repeatability*: this is a necessary, but not a sufficient condition;
- *invariance of the size distribution* to the delay time range, as long as the smallest range covers the set of decay times;
- *invariance of the peak positions* to the chosen range of particle sizes;
- *no peaks at the extremes* of the chosen size range;
- *consistency of the results* with the physical and chemical properties of the particles;
- *consistency* of the results with other sizing techniques. If data transformations are required they must be evaluated very carefully (see section 3).

5.3 Standardization

The International Organization for Standardization (ISO) published a draft paper that proposes to establish ''standard'' methods for the application of the DLS technique to the measurement of particle size distribution of samples with specified properties. Details of the proposal can be found in the publications of the subcommittee.[54] It should be noted that this publication is just a proposal subject to amendments. It presents a framework of design rules for DLS-based particle sizing that should yield results which are invariant to specific instruments or operators around the world.

6 INSTRUMENT DESIGN FOR DYNAMIC LIGHT SCATTERING

A typical DLS system may be broken down into several functional components which will be discussed separately. These are a light source, an optical system, a detector system and a digital correlator.

6.1 Light Source

Practical requirements for a sufficiently intense light source demand a narrow-band, polarized, monochromatic, CW laser. Table 2 summarizes the popular options available.

DPSS have become widely available within the last few years. Their wavelength is typically 532 nm (frequency doubled from powerful 1064 nm diode lasers) and their other properties match well with the requirements of DLS instruments.

6.2 Optical System

A lens focuses the laser beam down into the sample which is enclosed in a temperature-controlled scattering cell surrounded by a refractive index matching liquid. The scattered light is focused onto a PMT at an angle θ by another lens. Systems like this are constructed on a precision turntable with a stepper motor, and typically allow experiments to be conducted over a 10°–160° angular range.

6.3 Detector System

PMTs are almost universally used as detectors in DLS experiments (Table 3). These should have a low dark count and a high gain since most work is done in

Table 2 Summary of lasers commonly used in DLS installations

Type	Wavelength	Power	Size	Cost
HeNe	632.8 nm	5–35 mW	0.40–1.5 m	$500–$7000
Laser diodes	635–780 nm	5–100 mW	0.05–0.15 m	$300–$1200
Ar^+ (air cooled)	488–514.5 nm	~100 mW	1 m	$8000
Ar^+ (water cooled)	488–514.5 nm	~1.7 W	1.5–2 m	$16 000–$40 000
DPSS (Frequ. Doubled)	532 nm	10 mW–4 W	0.2–0.5 m	$3000–$40 000

DPSS, diode pumped solid-state lasers.

Table 3 Summary of PMTs commonly used in DLS

Type	Photo cathode	Dynodes (gain)	Dark count/Max. count	Comment
EMI 9863B	S20	14 (10^7)	40 cps/5 Mc	Red sensitive, QE: 3–4%
EMI 9130	S20	11 (10^6)	40 cps/1 Mc	Red sensitive small tube
Ham R464	Bialkali	12 (6×10^6)	5 cps/2 Mc	Quartz window for UV

the single photon counting regime. A comparatively new development is the single photon counting mode (SPCM) by EG&G[55] which incorporates an avalanche photo diode (APD), active reset and quenching electronics and a Peltier-type temperature controller in a small package. This author investigated the properties of the APD (supplied then by RCA Canada) in 1985 and found that they were not well suited for DLS applications owing to the lack of active quenching and the lack of an integrated temperature control for the semiconductor junction (unpublished). Brown[56] developed the required circuits and successfully implemented APDs into small fiber-optic-based DLS devices. New SPCMs can replace PMTs in many applications, particularly for wavelengths of more than 680 nm (near infrared).

6.4 The Digital Correlator

The correlator has become the device of choice to generate the raw data in a DLS experiment, although the early experiments mostly employed ''wave analyzers'' or ''spectrum analyzers''. (Today only one commercial instrument[32] still performs DLS particle sizing in the frequency domain by employing a real-time spectrum analyzer.) The basic design of a correlator is really very simple and was originally used at the Royal Radar Establishment, UK[57] (now Defence Evaluation and Research Agency) to recover radar signals that are deeply buried in noise. This instrument was commercialized by (then) Precision Devices, (now) Malvern Instruments,[58] in the early 1970s. The ACF is formed by recording the number of photons arriving in each sample time, maintaining a history of this signal over a large range of sample times (time series), multiplying the instantaneous and the delayed signal for a range of time delays t_d (the ''channels'') and accumulating these products. In the past most designs employed a multibit shift register to maintain a record of photon counts, as shown in Figure 4. In modern nonlinear correlators shift registers have been replaced by fast memories, allowing very flexible channel configurations with dynamic ranges that exceed 10 decades of time. Individual design details may be gathered from the manufacturers' literature.

Figure 5 shows an example of a complete standalone DLS-based, commercially available instrument that incorporates all of the above mentioned optics, electronics and data processing.

7 EXAMPLES OF DYNAMIC LIGHT SCATTERING MEASUREMENTS

7.1 Particle Size Distributions

The majority of applications for DLS in particle sizing are the rapid routine measurements of mean sizes in QC work. Manufacturers of latexes, pigments, emulsions, micelles, liposomes, vesicles, sils and silica can track the consistency of the desired particle sizes rapidly and accurately, independent of different operators and different instruments anywhere in the world. Often a bimodal distribution characterizes a sample better and is actually expected from the known chemistry of the sample. In such cases $G(\Gamma)$ will contain two modes that can be separated if their size ratio is at least 1:2 and the relative intensities are similar. Samples that tend to coagulate are easily tracked by DLS. Although the exact size distribution cannot be determined, the first and second moments are very sensitive to any changes in the distribution and give an immediate and accurate response. DLS-based particle sizing is also widely used for biological samples such as bacteria, viruses, proteins, DNA, etc. Many applications are in crystal growth and polymer research. The following few examples illustrate the breadth of DLS-based size measurements.

- Spontaneous vesicle formation in a biological surfactant (ganglioside GM3) was investigated by L. Cantu and M. Corti.[59]
- Studies of BSA and lysozyme, very low molecular weight proteins, were conducted by H. Dhadwal et al.[60]
- Protein (lysozyme) crystallization was investigated by Mikol et al.[61]
- Submicron emulsion systems were measured by Herb et al.[62]
- Liposome production is monitored by DLS in QC and research by the Avestin Corp.[63]
- B. Weiner[44] et al. used a fiber optic backscattering device to observe particle–particle interaction in highly concentrated latex suspension.
- Particle sizing related research on non-ergodic systems have been published by van Megen.[64] DLS was applied to the glass phase of nonaqueous suspensions of sterically stabilized colloid spheres.
- A widely used industrial process, hydro metallurgical solvent extraction, was investigated by Neuman[65] et al., applying the DLS technique to very small particles in the region of 2 nm.
- Caldwell[66] investigated emulsions by employing DLS and sedimentation field flow fractionation (SFFF) methods in a complementary mode. SFFF provides for a high-resolution fractionation of the sample and DLS measures the sizes without the need to know the density of the sample.
- Multiangle particle sizing and its associated data transformation have been investigated by Cummins.[67] If the sample is very clean, the multiangle constraint can be a powerful conditioning for the inversion matrix to stabilize the set of $G(\Gamma)$.
- Auweter et al.[68] published on-line measurements with a one-fiber backscattering device as early as 1985. Their experiments demonstrated the feasibility of such fiber optics in a hostile environment.

8 COMPARISON WITH OTHER PARTICLE SIZING METHODS

Different techniques yield different ''sizes'' for the same particles simply because they employ different physics for the measurement. DLS, for example, will easily detect a few large particles among many small ones. Also, the DLS technique is *absolute* and there are no adjustable parameters available for a ''calibration''. Often the term

Table 4 Comparison of particle sizing techniques

Technique	Resolution	Dyn. range	Calibration	Mass balance	Time/Sec
DLS (PCS)	Low	1:1000	Not required	Intrinsic	2–15
Particle counters	Very high	1:10	Required	Must be verified	8–20
Microscopes	Very high	1:10	Required	Not verifiable	>30
Laser diffraction	Low	1:300	Not required	Intrinsic	2–5
SLS (Mie)	Low	1:10	Required	Intrinsic	2–5
Time of transition	High	1:10	Required	Must be verified	8–30
Sedimentation	Very high	1:30	Not required	Intrinsic	5–30
Centrifugation	Very high	1:30	Not required	Intrinsic	5–30
SFFF	Very high	1:100	Not required	Must be verified	8–20
HDC	Very high	1:10	Required	Must be verified	8–20

HDC, hydrodynamic chromatography.

''calibration'' is confused with the ''validation''. As with any instrument, its proper operation must be verified with known samples, but no adjustments for calibration can be utilized to achieve the ''correct'' result. This is in contrast to microscopes or ''particle counters'' for which a calibration must be performed (Table 4).

Dynamic ranges are valid for one measurement without changing optics, capillaries, etc. All the techniques cover at least part of the DLS range of particle sizes: ca. 0.001–3 μm. Measurement times are typical and depend on the breadth of the distribution, absolute size and physical properties of the particles (e.g. density), desired precision, etc. The widely used Fraunhofer diffraction instruments are advertised as covering a size range of as low as 20 nm to several millimeters. These devices actually combine two distinct instruments: one that is based on diffraction theory (low-angle scattering) with d^2 weighting and one based on Mie scattering with d^6 weighting. This explains the large dynamic range that is advertised for these instruments but because of the different weighting and low resolution a true merging of the mass distribution is impossible, regardless of the claims in the manufacturers' literature. Thus comparisons between DLS and ''Fraunhofer'' sizing results ought to be performed with great caution by carefully evaluating the experimental conditions and examinating the mathematical transformations that are required.

9 NEW DEVELOPMENTS

9.1 New Correlator Developments

In the last several years new correlators have become available, which are remarkably compact, have a large dynamic range in delay time and can accommodate many more counts in a given sample time. These developments are a direct result of the availability of more versatile, higher speed and higher density integrated circuits, and novel approaches to the implementation of the autocorrelation operation. Based on designs by K. Schätzel[22,23] the ALV company[69] is developing a correlator with 16 inputs and a minimum sample time of 800 nsec (50 nsec for a single input). Brookhaven[70] is developing a new correlator that incorporates sophisticated multiple digital signal processing (DSP) in real time. Flexible Instruments[71] offers a range of application-specific integrated circuits based correlator boards. Correlators are really nothing more than specialized DSP instruments, regardless of their specific designs. As such the design of these devices benefits from the relentless improvement in the semiconductor industry: higher speed, more integration, lower power, physically smaller and higher gate densities. These new correlators will extend the application of DLS and improve existing applications.

9.2 Solid-state Lasers

These diodes have become reliable and stable enough to be used in routine DLS based measurements. Higher power DPSS lasers are beginning to replace Ar^+ in many installations. Near infrared lasers (>780 nm) at 100 mW and more can be used in combination with APDs[55] and are particularly well suited for efficient coupling into single-mode fiber optics (large wavelength).

9.3 Fiber Optics

Bulk optics are being replaced more and more with fiber-optic devices. Ricka[72] has shown that single-mode fibers have the unique property of acting as spatial filters yielding high ACF intercepts near the theoretical maximum without sacrificing high intensities that are received by the detector. Ongoing developments will improve the efficiency of launching laser beams into single-mode fibers (currently about 40%) and make polarization-preserving filters more widely available.

9.4 New Applications

- Diffusing wave spectroscopy (DWS): in these new experiments by D. Pine and D. Weitz[73] a ''length parameter'' is calculated from the initial fast decay of the ACF from multiple scattered light, extending DLS applications to samples with higher particle concentrations.
- W. Meyer et al.[74,75] at the National Aeronautics and Space Administration (NASA) designed a promising set-up that employs two detectors and two single mode fibers that are located a tiny distance apart such that the scattered light originates most likely from one speckle. The cross correlation function (CCF) of the signals from the two detectors yields the proper D_T and hence particle size.
- Based on original work by Dhadwal et al.,[76] the commercially available FOQELS instrument from Brookhaven Instruments Corp.[70] utilizes two single-mode fibers at a 155° backscattering angle.
- ALV[69] is currently developing a dual-fiber instrument for backscattering at a 173° angle.

Continuing development of fiber-optic technology will make it possible to construct compact, multiangle light-scattering spectrometers for DLS (and SLS) with no moving parts.

10 CONCLUSION

As any other particle sizing technique, DLS has advantages and disadvantages and it is particularly important to use it strictly within the framework of physical laws, if meaningful results are to be obtained. The following is a short compilation of the advantages and disadvantages of DLS-based particle sizing.

10.1 Disadvantages

- It does not produce a high-resolution histogram of the size distribution.
- Like other nonimaging techniques an equivalent sphere diameter is usually, although not always, assumed. Shape information is not easily obtained.
- When proper measurements are made, the parameters which are most often obtained are the inverse z-average moments of the size distribution, not the usually reported parameters of a size distribution.
- Dust can make measurement and interpretation difficult.

10.2 Advantages

- Measurements are fast, from seconds to minutes.
- The technique is absolute, from first principles. Calibration with a known size distribution is not necessary to get answers.
- Very small quantities of sample can be measured.
- Any suitable suspending liquid can be used provided it is nonabsorbing, relatively clear and not too viscous.
- The technique is applicable from about 0.001 to several microns.
- Instrumentation is commercially available for both research and QC measurements with automation including data analysis.
- Although the interpretation of particle size is least ambiguous with a narrow distribution, an effective diameter and polydispersity index are measurable even with broad distributions.

In order to provide an introduction to the DLS technique, the physical basis of the technique and the associated instrumentation has been discussed. Several new developments in the instrumentation have been described which have the potential for fundamentally changing the way DLS measurements are made and lead to many new applications of the technique. The commercial importance of DLS as a submicrometer particle sizing tool ensures that technological developments will occur rapidly in this field.[32,55,58,63,69,70,71,77–79]

LIST OF SYMBOLS

a	Instrument constant
A_{coh}	Coherence area
A_{det}	Detector area
A/D	Amplifier/Discriminator
Ar^+	Argon Ion laser
B	Baseline of the intensity ACF $G^{(2)}(t_d)$ before normalization
$B(c)$	Concentration factor
c	Particle concentration
cps	Photon counts per second
$g^{(1)}(t_d)$	Normalized correlation coefficient at delay t_d (Field ACF)
d	Particle diameter
d_{det}	Diameter of the detector area
$\langle d_n \rangle$	Mean diameter by number
d_p	Distance between particles
d_{sr}	Diameter of scattering area
d_Z	z-average diameter (the next higher weighting after mass: intensity)
D_T	Translational diffusion coefficient
$g^{(1)}(t_d)$	First-order correlation coefficient at delay t_d
$G(\Gamma)$	Line width distribution function
HeNe	Helium Neon laser
$\langle I(q) \rangle$	Time averaged intensity at wave vector q
k_B	Boltzman constant
K	Optical constant
M	Particle mass
n	Refractive index
N	Number of particles
$P(\Theta)$	Particle form factor
q	Wave vector
Q	Polydispersity index
R	Distance between scattering volume and detector
t	Time
t_d	Delay time between multiplication terms for $C(t_d)$
T	Absolute temperature (Kelvin)
Γ	Line width of scattered light (radians/sec)
$\langle \Gamma \rangle$	Average line width
$\eta(T)$	Viscosity of the medium in which particles are suspended (Poise)
Θ	Scattering angle
λ	Wavelength of light in the suspension medium (λ_0/n)
λ_0	Wavelength of light in vacuo
μ_i	Moments of a distribution ($i = 1, 2, \ldots$)
τ	Decay constant for exponential forms of $C(t_d)$; $C(\tau) = C(0)/e$

ABBREVIATIONS AND ACRONYMS

ACF	Auto Correlation Function
APD	Avalanche Photo Diode
CCF	Cross Correlation Function
DLS	Dynamic Light Scattering
DPSS	Diode Pumped Solid-state Lasers
DSP	Digital Signal Processing
DWS	Diffusing Wave Spectroscopy
HDC	Hydrodynamic Chromatography
IFS	Intensity Fluctuation Spectroscopy
ISO	International Organization for Standardization
NASA	National Aeronautics and Space Administration
NNLS	Non-negative Least Square
PCS	Photon Correlation Spectroscopy
PMT	Photo Multiplier Tube
QC	Quality Control
QE	Quantum Efficiency
QELS	Quasi-elastic Light Scattering
SFFF	Sedimentation Field Flow Fractionation
SLS	Static Light Scattering
S/N	Signal-to-noise Ratio
SPC	Statistical Process Control
SPCM	Single Photon Counting Mode
TEM	Transmission Electron Microscope

Particle size analysis by sedimentation is one of the most important techniques of analysis. The principle is based on the fact that it is possible to draw conclusions about the geometrical dimensions (size) of the particles from the speed of their movement in a fluid. In the past many different apparatuses were developed. Nowadays, methods that allow quick, automatic measurement are most popular.

This article consists of two general sections valid for all methods: the first concerns the undisturbed and disturbed movement of particles in a fluid at rest, and the second concerns the dispersion of solids in liquids.

The methods described are divided in gravitational methods and methods used in a centrifugal field, respectively. Finally, the appendix gives a list of liquids and dispersing agents valid for measurement.

1 INTRODUCTION

It is well known that the measuring principle of sedimentation methods is partially based on the fact that it is possible to make conclusions about the geometrical dimensions (size) of particles from knowledge of the speed of their movement in a fluid. Therefore, the temporal and spatial changes in the particle concentration in a sedimenting system provide substantial information on the quantitative distribution of particle sizes. The measurement of such distributions is called sedimentation analysis; it requires the theoretical understanding and experimental handling of the following two phenomena:

- the connection between sedimentation velocity and particle size depending on the material properties of the system and the other conditions in the sedimentation vessel,
- the connection between the concentration distribution of the solid observed after time t and its size distribution. This requires methods that both indicate concentration changes and allow calculation of the distribution from the measured data.

The methods of sedimentation analysis are grouped according to the following fundamental criteria:[1–13]

- according to the position of particles at the beginning of measurement
  - homogeneous methods: the particles are uniformly distributed over the whole sedimentation space
  - line start methods: the particles in the beginning are concentrated in a thin layer on top of the solid-free medium
- according to the place of quantity measurement
  - incremental methods: the amount (concentration) of solids in a thin suspension layer (measurement level) is measured
  - cumulative methods: the total amount of solids above or below a measurement level is measured
- according to the force field
  - gravitational methods
  - centrifugal methods.

In effect, there are eight groups of sedimentation methods which, however, are not of equal practical significance. Methods widely and frequently used at the moment include the incremental and partially the cumulative methods in a gravitational or centrifugal field.

For incremental methods, the mass or volume distribution are directly measured in the one-layer (suspension) method, and the corresponding frequency distribution is measured in two-layer (line start) methods. In contrast, the mass or volume distribution are obtained for the two-layer scheme in the case of cumulative methods. For a cumulative one-layer scheme, the distribution has to be determined by differentiation on the basis of the cumulative measurement result.

A further subdivision of the sedimentation methods is based on the type of principle for measuring the solids concentration:

- Gravimetric determination (mass)
  - weighing of the solid mass contained in the suspension sample (pipette methods, decanting)
  - weighing of the solid mass sedimented on a balance pan (sedimentation balances)
- Measurement of the absorption of electromagnetic radiation
  - light attenuation (photometric extinction methods)
  - attenuation of γ-radiation
- Measurement of suspension density
  - manometer methods
  - diver methods (areometers, divers)
- Measurement of the backscattering of β-radiation.

Again, these principles of measurement are not all of the same importance for the different types of sedimentation analysis. A large number of known methods (several reviews can be found in the literature[1–15]) can be found in granulometric measurement technology. The following advantages may have played a decisive role in this:

1. Like all classification methods (and unlike the nonfractionating methods), sedimentation analysis gives the proportion of particles that are smaller than the smallest measurable particle size.
2. Very simple and inexpensive devices can be used which can even be built by the user.
3. Frequently measurement is possible without the disturbance of interference to the system.
4. At a higher cost, fast automatic devices can be employed.
5. The range of measurement can be extended below 0.1 µm if a centrifugal field is used.

Disadvantages particularly in comparison with modern nonfractionating methods are:

1. There are numerous subjective and objective sources of error.
2. The maximum particle size is usually approx. 50 µm; larger particles can be measured only in special cases.
3. The time of analysis during which numerous conditions have to be kept constant is relatively long in comparison with modern nonfractionating methods.

The latter problem has been most responsible for the decline in use of a considerable number of previously widespread devices and methods. This is especially the case for methods that do not allow for a decisive reduction in the sedimentation height, such as sedimentation balance, diver, and so on.

In the following chapters we will deal with particle movement in a fluid, dispersion problems and then with some of the techniques of sedimentation analysis.

2 PARTICLE MOVEMENT IN A FLUID AT REST

2.1 Undisturbed Particle Movement

Undisturbed sedimentation takes place if the particles in a fluid of infinite expansion are separated by such distances that any mutual influence can be excluded.

2.1.1 Stationary Movement of Spherical Particles

In the stationary case, a particle moves with constant velocity U relative to the surrounding medium. There is an equilibrium between the weight G_P minus buoyancy A_P and the drag force W_P exerted on the particle by the medium (fluid), Equation (1):

$$W_P = G_P - A_P = V_P(\rho_s - \rho_m)g \tag{1}$$

Furthermore, according to Newton, Equation (2):

$$W_P = \tfrac{1}{2} c_W F_P \rho_m U^2 \tag{2}$$

From Equations (1) and (2), the fundamental equation of stationary particle movement in a fluid is obtained, Equation (3):

$$U^2 = \frac{2\Delta\rho g}{c_W \rho_m} \frac{V_P}{F_P} \tag{3}$$

For spherical particles (Equation 4) with

$$V_P = \frac{\pi}{6}x^3; \quad F_P = \frac{\pi}{4}x^2 \tag{4}$$

Equations (2) and (3) become Equations (5) and (6)

$$W_P = \frac{\pi}{8}\rho_m c_W x^2 U^2 \tag{5}$$

$$U^2 = \frac{4}{3}\frac{\Delta\rho g}{c_W \rho_m} x \tag{6}$$

The particles are usually assumed to be spherical in shape. This, however, leads to a fundamental discrepancy with respect to the real conditions in most cases, because the size of a particle of any shape is described by the dimensions of a solid sphere which has the same hydrodynamic behavior as the particle. It is clear that such an approach is acceptable only as long as the shape of the particle does not change between measurements; otherwise, grain-shape characteristics have to be included in the description of the hydrodynamics of the particle.

For the entire size range, the dependence of the drag coefficient on the sedimentation rate of spheres can be determined only empirically. Some values are collected in Table 1.

The curves are shown in Figure 1, with the Reynolds number, Equation (7)

$$Re = \frac{\rho_m U x}{\eta} \tag{7}$$

on the axis of abscissa.

An exact physical description of the dependence $c_W(Re)$ has so far been impossible because the Navier–Stokes differential equations (see Happel and Brenner,[17] and Lamb[18]) can be integrated only if certain terms are neglected, so that the solutions are always true only for a limited range of *Re* numbers.

By neglecting inertia terms in the Navier–Stokes equations, Stokes[19] in the middle of 19th century found

Table 1 Empirical drag coefficients for spheres according to Allen[16]

Re	c_W	$c_W Re^2$	c_W/Re	$c_W = 24/Re$ (Stokes)
0.01	2400	0.24	240 000	2400
0.02	1200	0.48	60 000	1200
0.05	484	1.21	9680	480
0.1	244	2.44	2440	240
0.2	123	4.92	615	120
0.5	51.4	12.85	102.8	48
1	27.2	27.2	27.2	24
2	15.0	60.0	7.5	12
4	8.33	133.3	2.083	6.0
5	7.12	178	1.424	4.8

20	2.74	1096	0.137	1.2
50	1.56	3900	0.0312	0.48
100	1.10	11 000	0.011	0.24

Figure 1 Drag coefficient plotted against Reynolds number.

the formula, Equation (8)

$$W_{St} = 3\pi\eta x U \tag{8}$$

for the drag force. This is equivalent to, Equation (9), (see Figure 1)

$$c_W = \frac{24}{Re} \tag{9}$$

With Equation (6), this gives the well-known "Stokes equation", Equation (10)

$$U = \frac{\Delta\rho g}{18\eta} x^2 \tag{10}$$

However, there are lower and upper limits for using the Stokes equation. If the Reynolds number and the particle size are very small and the latter is of the same order of magnitude as the mean free path of the fluid molecules, Equation (11)

$$L = \frac{3\eta}{\rho_m}\left(\frac{M_M}{3kTN_L}\right)^{1/2} \tag{11}$$

one can no longer assume that the fluid is a continuum. These conditions lead to a lower drag force and, consequently, to an increase in the stationary sedimentation velocity.

For liquids, the mean free path L of the molecules is about 10^{-9} cm. On the other hand, particles whose size is determined by the Stokes velocity are no smaller than approx. 10^{-6} cm (0.01 μm) so that the effect can be neglected in liquids. The situation is different with gases. Their mean free path is approx. 10^{-5} cm under normal conditions, that is the drag force must be corrected. The general type of this so-called "Cunningham correction" is given by Equation (12)

$$W = 3\pi\eta\frac{U}{C_L} \tag{12}$$

(terms for C_L see Table 2).

Table 2 Relationships for C_L in Equation (12)

$C_L =$	Ref.	Valid in the range
$\frac{(1+6AL/x)}{(1+4AL/x)}$	17, 20	
$1+\ 2.514+0.8\exp\ -0.55\frac{x}{L}\ \ \frac{L}{x}$	21	$2\frac{L}{x}<1$
$1+2A\frac{L}{x}$	16, 22	$A=0.7\ldots1.4$
$\frac{1}{(1-2AL/x)}$	17, 23	
$4.49\frac{L}{Bx}$	16	$2\frac{L}{x}>1$
$3\frac{L}{Bx}$	24	$B=1\ldots1.4$

Generally, correction is necessary for particles $< 10\,\mu m$ in air. Without any correction, the measured values $Q_3(x)$ are shifted in the direction of the coarser range with respect to the actual particle size distribution.

For large Reynolds numbers the empirical drag coefficient is larger than that predicted by Stokes, therefore the settling velocities in sedimentation will be smaller than expected. This means that the measurement values $Q_3(x)$ are shifted in the direction of smaller sizes. In general, a size error of approx. 1–2% (equivalent to an error in the drag coefficient of approx. 3–5%) can be accepted even for very narrow distributions. Then the upper limit of the acceptable Reynolds numbers is between 0.25 and 0.5 for these values.[13]

A considerable number of equations have been proposed in the literature to enable further extension towards higher Reynolds numbers.[13,25] On the whole, they all have the fundamental structure, Equation (13)

$$c_{W,i} = \frac{24}{Re} B_i \tag{13}$$

For examples of B_i see in Table 3.

The value of the maximum permitted Reynolds number Re_{max} applies to maximum particle size errors of $\pm 1\%$ and $\pm 2\%$ respectively. They were calculated on the basis of the difference between c_W according to Equation (13) and empirical c_W values (Allen,[16] Bernhardt;[31] see Table 1). The maximum particle size x_{max} can be calculated by, Equation (14)

$$x_{max}^3 = \frac{18\eta^2}{\rho_m \Delta\rho g} B_i Re_{max} \tag{14}$$

Table 3 also shows the case of quartz in water.

Unfortunately, some of the equations (Proudman and Pearson,[28] Schiller and Naumann[30]) do not allow for an analytical solution of the sedimentation velocity U or the particle size x, so that an iteration has to be programmed before they can be used.

On the other hand, in such cases the empirical calculation can possibly be done without an analytical approximation equation.

In 1933 Schiller and Naumann[30] developed a graphical method which later was improved and modified by several authors.[32,33] It is based on the calculation of either Equation (15)

$$c_W Re^2 = \frac{4\Delta\rho g \rho_m x^3}{3\eta^2} = \frac{4}{3} Ar \tag{15}$$

or Equation (16)

$$\frac{c_W}{Re} = \frac{4\Delta\rho g \eta}{3\rho_m^2 U^3} = \frac{4}{3}\frac{1}{Lj} \tag{16}$$

depending on whether the particle size x or the sedimentation velocity U is given. These values are points on the empirical curve c_W/Re ($c_W Re^2$) which are represented in Figure 2 (for further values, see e.g. Clift[25]).

Because of the large error in the graphical method, the following approximation, Equation (17) is useful for a numerical calculation (see Davies[21]):

$$Re = 4.1667\times10^{-2}K - 2.336\times10^{-4}K^2 + 2.0154\times10^{-6}K^3 - 6.9105\times10^{-9}K^4 \tag{17}$$

where $K = c_W Re^2$

Table 3 Equations of $c_W(Re)$

Author	Ref.	B_i in Equation (13)	Re_{max}		x_{max} (μm)	
			$f_x = 1\%$	$f_x = 2\%$	$f_x = 1\%$	$f_x = 2\%$
Stokes	19	1	0.25	0.5	65	82
Oseen	26	$1+0.1875\,Re$	0.75	1.5	104	129

Möller	29	$1+0.139\,Re$	2.5	3.5	155	180
Bernhardt	13	$1+0.0917\,Re$	0.7	10	94	277
Schiller and Naumann	30	$1+0.15\,Re^{0.687}$	5	1000	201	2728

Figure 2 Empirical curve c_W/Re plotted against $c_W Re^2$.

It fits very well in the range $Re \leq 4$ ($c_W Re^2 \leq 133$): the drag error remains $\leq 0.6\%$.[31]

To calculate U for a given x (outside the Stokes range, i.e. for large Re numbers):

1. Calculate $c_W Re^2$ according to Equation (15), take out the c_W/Re value from Figure 2 and calculate U by means of transformed Equation (16) or
2. Calculate $c_W Re^2$ according to Equation (15), calculate Re by means of Equation (17) and then U by means of Equation (7).

2.1.2 Nonstationary Movement of Spherical Particles

If a particle in a fluid is subject to an acceleration, the process is called nonstationary movement. Such a case is given when, in a fluid at rest, the particle is brought from its rest position ($t = 0$; $v = 0$) to its terminal velocity of settling ($t = \infty$; $v = U$). In contrast to the stationary case, the (inertial) force acting on the particle is now equal to the difference between its weight minus buoyancy and the drag force of the medium, Equation (18)

$$m_P \frac{dv}{dt} = G_P - A_P - W_P \tag{18}$$

In the creeping flow range the instantaneous drag depends not only on the instantaneous velocity and acceleration but also on the conditions prevailing during the formation of the flow. For the drag force, the simple Equation (8) is no longer true and has to be replaced by Equation (19)

$$W_P = 3\pi\eta x v + \frac{1}{2} V_P \rho_m \frac{dv}{dt} + \frac{3}{2} x^2 \sqrt{\pi\eta\rho_m} \int_0^t \frac{dv/ds}{\sqrt{t-s}}\, ds \tag{19}$$

according to Clift et al.[25]

The first term is the Stokes drag for stationary motion at instantaneous velocity. The second term is the ''added mass'' or ''virtual mass'' caused because the acceleration of the particles requires acceleration of the fluid. The third term includes the ''Basset history integral'' representing past acceleration, where $(t - s)$ is the time elapsed since the past acceleration.[25] The substitution of Equation (19) into Equation (18) produces a differential equation with some difficulties for its practical application.[34] Therefore the solution without the Basset term is used in most cases:

$$\frac{v}{U} = 1 - \exp\left\{ -\frac{18\eta}{\rho_s + \rho_m/2} \frac{t}{x^2} \right\} \tag{20}$$

The time t_{99} for which $v/U = 0.99$ is then (without the Basset term):

$$t_{99} = 0.2558 \frac{\rho_s + \rho_m/2}{\eta} x^2 \tag{21}$$

This approximation is sufficient for solids in gases ($\rho_s/\rho_m > 1000$) only. In the case of large solid particles in liquids ($\rho_s/\rho_m < 100$) the Basset term must not be neglected; according to the calculations of Clift et al.[25] Equation (22) holds (including the Basset term):

$$t_{99} \approx 800 \frac{\rho_m x^2}{\eta} \tag{22}$$

Large particles with sizes near the upper border of the Stokes range need a few seconds to come close to the terminal velocity from the initial quiescent state. As an example, quartz particles with $x = 0.1$ mm in water give $t_{99} = 8$ s according to Equation (22).

2.1.3 Stationary Movement of Nonspherical Particles

2.1.3.1 Fundamentals Hydrodynamic concepts not related to a sphere have to be related to a different defined geometric shape, which should apply flexibly to all existing shapes from a very thin plate to a very long rod. Such a shape is the ellipsoid with the half axes a, b, c for which the equations of motion have long been known.[17,18,35,36] For the important borderline cases of the ellipsoid, that is, plates ($a = b > c$) and rods ($b = c < a$) Gans[36] gives complete analytical solutions for the sedimentation of the particles in the direction of either their a-axis or their c-axis. For these shape types Equations (23) and (24) hold

$$U_P = \frac{2}{9} \frac{\Delta\rho g a c}{\eta} R_P \quad \text{(for plates)} \tag{23}$$

$$U_R = \frac{2}{9} \frac{\Delta\rho g c^2}{\eta} R_R \quad \text{(for rods)} \tag{24}$$

Table 4 Factors R_P and R_R in Equations (23) and (24)

Shape		R	Equation
Plates $a = b > c$		c-direction: $R_{P,c} = 0.750\ (A_1 \arccos p + B_1)$ a-direction: $R_{P,a} = 0.375\ (A_2 \arccos p - B_1)$	(25) (26)
Rods $b = c < a$		c-direction: $R_{R,c} = 0.375\ (A_3 \ln C - B_2)$ a-direction: $R_{R,a} = 0.1875\ (A_4 \ln C - B_2)$	(27) (28)

$A_1 = D(1-2p^2)$; $A_2 = D(3-p^2)$; $A_3 = D(2-p^2)$; $A_4 = D(2-3p^2)$. $B_1 = p/E$; $B_2 = 2/E$; $C = (1+E^{1/2})/(1-E^{1/2})$; $D = E^{-3/2}$; $E = (1-p^2)$; $p = c/a$.

Table 5 Values of R_P and R_R according to Gans[36] and Happel and Brenner[17]

$p = c/a$	Plates		Rods	
	$R_{P,a}$	$R_{P,c}$	$R_{R,a}$	$R_{R,c}$
0	1.767	1.178	∞	∞
0.01	1.752	1.178	7.197	4.348
0.1	1.631	1.174	3.764	2.617
0.2	1.516	1.160	2.799	2.108
0.4	1.335	1.125	1.914	1.606
0.6	1.196	1.084	1.467	1.326
0.8	1.139	1.041	1.191	1.138
0.9	1.041	1.019	1.091	1.063
1	1	1	1	1

The terms for the factors R_P and R_R for both directions c and a can be taken from Table 4.

Table 5 also contains some values of R_P and R_R for the two special sedimentation directions.

For spherical shape ($p = 1$), all R values assume the value 1 so that Equations (23) and (24) become identical with the Stokes formula.

According to Gans,[36] for very thin plates $p \ll 0.2$ there is an acceptable approximation, Equation (29)

$$R_{P,c} = \frac{3\pi}{8} = 1.178 \tag{29}$$

from which the well-known formula of the drag force, Equation (30)

$$W_{P,c} = 16\eta a U \tag{30}$$

is derived.[18,37] This, however, is true only for thin plates whose large half axis a is in the horizontal plane, and which sediment in the direction of their short half axis c (vertically). Experimental investigations concerning the validity and applicability of these theoretical concepts have frequently been published in the literature.[32,33,37–43]

The sedimentation directions discussed so far relate to the position of the a-axis or c-axis of the spheroids in the direction of sedimentation. In reality, however, every particle orientation has the same probability at the beginning of sedimentation. Theoretically, this situation remains unchanged in the range of the creep flow for the whole sedimentation path.[17]

Figure 3 shows schematically a spheroid, whose a-axis is inclined towards the horizontal x-axis by the angle α.

Dependent on its inclination with respect to the horizontal, forces (not represented) act on the particle in such a way that a resulting velocity U with the horizontal and vertical components U_x and U_z is formed. Equations (31–33) are valid:[36,44]

$$U^2 = U_a^2 \sin^2\alpha + U_c^2 \cos^2\alpha \tag{31}$$

$$U_x = (U_a - U_c) \sin\alpha \cos\alpha \tag{32}$$

$$U_z = U_a \sin^2\alpha + U_c \cos^2\alpha \tag{33}$$

Figure 3 Velocities for an arbitrary position of the particle.

Table 6 Velocity ratios U/U_z and U_x/U_z of extremely thin plates and rods dependent on their angular position

α (°)	Plates $p = 0, U_c/U_a = 0.667$		Rods $p = 0, U_c/U_a = 0.5$	
	U/U_z	U_x/U_z	U/U_z	U_x/U_z
0	1.000	0	1.000	0
10	1.004	0.086	1.013	0.167
20	1.011	0.153	1.041	0.289
30	1.019	0.195	1.059	0.347
40	1.021	0.206	1.059	0.348
50	1.019	0.193	1.047	0.310
60	1.012	0.159	1.031	0.248
70	1.006	0.112	1.015	0.171
80	1.002	0.058	1.004	0.087
90	1.000	0	1.000	0

U_a and U_c are the velocities in the extreme positions $\alpha = 90°$ and $\alpha = 0°$. Table 6 gives some values of U/U_z and U_x/U_z dependent on the angle α.

It is evident that the horizontal component U_x can assume considerable values for extreme particle shapes. In most cases, however, the differences between the resultant U and its vertical component U_z are negligible. Experimental investigations of plates[43] and rods[44] fully confirm this theory.

2.1.3.2 Shape Factors Knowledge of the relationship between the geometrically defined shape of a particle and its hydrodynamic behavior suggests that it must be possible to obtain characteristics of the shape of real particles from their sedimentation velocity. There are two basic definitions of such characteristics; either the drag force or the sedimentation velocity of a particle of the same volume is corrected.

Dynamic particle shape factor κ, Equations (34) and (35)

$$W = 3\pi\eta U x_v \kappa \tag{34}$$

and

$$\kappa = \frac{W}{W_v} = \frac{U_v}{U} \tag{35}$$

where x_v is the diameter of a sphere which has the same volume as the particle and U_v is the stationary sedimentation velocity of a sphere of the same volume.

Shape correction factor K, Equations (36) and (37)

$$U = \frac{\Delta\rho g}{18\eta} x_v^2 K \tag{36}$$

and

$$K = \frac{U}{U_v} = \frac{1}{\kappa} \tag{37}$$

x_v has to be determined if the equations of motion are to be used for particle shape definition. Again, the approximation to an ellipsoid has proved highly useful since the equations of motion are well known for this geometrical body. The basis for this approach are the work of Heiss and Coull[38] for factor K and later of Walkenhorst[39,40] for κ.

Taking into account the equality of the volume of sphere and ellipsoid, for any orientation of the particle, K_P and K_R are obtained,[44] Equations (38) and (39)
for plates

$$K_P = \frac{U_z}{U_v} = p^{1/3}[R_{P,a}\sin^2\alpha + R_{P,c}\cos^2\alpha] \tag{38}$$

for rods

$$K_R = p^{2/3}[R_{R,a}\sin^2\alpha + R_{R,c}\cos^2\alpha] \tag{39}$$

There have been many attempts to correlate the shape factors defined by the particle geometry and the hydrodynamic behavior (see the overview by Pahl et al.[213]). Wadell[46] and Heywood[32,47] reported this in great detail. Wadell[46] holds the view that for sedimentation processes, the proportion of the surface area to the volume is the decisive factor. This leads him to the shape factor called sphericity, Equation (40)

$$\psi_{Wa} = \frac{x_V^2}{x_A^2} \tag{40}$$

where x_A is the diameter of the sphere of equal surface area.

Also by comprehensive experiments with isometric particles, Pettyjohn and Christiansen[41] found the empirical relationship between ψ_{Wa} and the shape factor K, Equation (41)

$$K = 0.843 \log\left(\frac{\psi_{Wa}}{0.065}\right. \tag{41}$$

Another shape factor, also defined by Heywood[32] was called the volume coefficient, Equation (42)

$$k = \frac{V_P}{x_F^3} \tag{42}$$

where x_F is the equivalent projected area diameter.

Heiss and Coull[38] eventually found empirical equations for the shape factor K; they also included, in addition to ψ_{Wa}, a new factor which was called circularity, Equation (43)

$$\psi_{HC} = \frac{x_V}{x_F} \tag{43}$$

2.2 Disturbances and Influences on Particle Movement

2.2.1 Apparent Distributions

Numerous influences on the sedimentation motion mean that the true distribution is not measured, only an apparent one. Consequently, a particle system presumed to be monodisperse is then measured as an apparently polydisperse system. Factors contributing to this effect are:

- Factors caused by the particles
  - deviation from the spherical shape
  - Brownian motion of the particles
  - heterogeneity of the solid
- Factors caused by the method
  - limitations of the vessel
  - extension of the measuring gap.

The question of great practical interest is, what distributions are to be measured finally if the starting distribution is already polydisperse? This problem can be solved by the strict application of the ''concept of apparent distributions'' developed by Bernhardt.[48] It allows passage from the monodisperse case to the polydisperse one.

What is the principle of the concept mentioned? The explanation is given in Figure 4.

Figure 4 Ideal and real sedimentation.

The upper part of the figure shows the principle of the incremental sedimentation analysis: the solid particles are homogeneously distributed in a vessel at the time $t = 0$; the solid concentration is constant at every depth h as shown below. A sensor, situated at a depth h_M, measures the solid concentration there as a function of time. In the ideal case, the highest particle layer of a monodisperse system just reaches the measuring depth h_M at the time $t = t_1$. This leads to a concentration jump at this point and the cumulative distribution represents monodispersity exactly. In the real case, however, after t_1 there is a more or less diffuse border near the measuring plane. Consequently, the measured course of concentration is as shown in Figure 4, which results in an apparent polydisperse distribution.

2.2.2 Particle Shape

To estimate the influence of the particle shape on the results of the sedimentation analysis, we assume:

1. The particle system is monodisperse with constant particle shape.
2. It can be described by spheroids as explained above in section 2.1.3 (c or a and p = const.).
3. The actual particle orientation does not change during the sedimentation (α = const.).

In Figure 5(a) such a particle system is schematically represented in its initial state ($t = 0$); for the sake of simplicity, particles of the same orientation were arranged within one column.

After a certain period of time $t = t_1$, the picture becomes similar to that in Figure 5(b): the particles sedimenting in a-direction have traversed a longer distance than those with a smaller angle ($\alpha < 90°$). Therefore, unlike the case of monodisperse spheres, there will be no distinct concentration jump in the depth h_M (on the measurement level) but there will be a concentration change whose course will be reflected as an apparent particle size distribution $Q_3(x_S)$ as a result of the measurement. Owing to the equal probability of all

Figure 5 Sedimentation of nonspherical particles.

angular positions, Equation (44) holds

$$Q_3(x_S) = \frac{c}{c_0} = \frac{\alpha}{\alpha_{max}} = \frac{2\alpha}{\pi} \tag{44}$$

The apparent Stokes particle size x_S is calculated by equating U_z (Equation 33) with Stokes equation. Then, for the two spheroids (plates and rods) an apparent distribution is obtained, Equation (45)

$$Q_3(x_S) = \frac{1}{\pi} \arccos S_{P,R} \tag{45}$$

where Equations (46–48) apply

$$S_P = \frac{2(x_S^2/x_a x_c) - R_{P,c} - R_{P,a}}{R_{P,c} - R_{P,a}} \tag{46}$$

$$S_R = \frac{2(x_S^2/x_c^2) - R_{R,c} - R_{R,a}}{R_{R,c} - R_{R,a}} \tag{47}$$

$$x_a = 2a;\ x_c = 2c \tag{48}$$

If x_S is related to the median $x_{S,50}$ of the distribution, Equations (49) and (50) follows

$$Q_3\left(\frac{x_S}{x_{S,50}}\right) = \frac{1}{\pi} \arccos T_{P,R} \tag{49}$$

where

$$T_P = T_R = \frac{R_c + R_a}{R_c - R_a} \quad \frac{x_S^2}{x_{S,50}^2} - 1 \tag{50}$$

where R_a and R_c are according to Equations (25–28).

This distribution is graphically represented in Figure 6 for some values of $p = x_c/x_a$, starting with the smallest particle size $x_{S,c}$ (sedimentation in c-direction; $\alpha = 0°$) and ending with a maximum $x_{S,a}$ (sedimentation in a-direction; $\alpha = 90°$).

For thin plates ($p < 0.1$) the width of the apparent distribution can, to a rough approximation, be assumed to be independent of p for all practical cases. For thin rods (needles, fibers) the width of the distribution becomes larger and larger with decreasing p.

Which effect arises in the case of a polydisperse particle system is of practical interest, meaning for example that x_a is variable, and p is constant. Then the apparent distribution is, Equation (51)

$$Q_3(x_a, x_S) = \frac{1}{\pi} \int_{x_{a,min}}^{x_{a,max}} q_3(x_a) \arccos S_{P,R}\, dx_a \tag{51}$$

With Equation (51) we are able to estimate the modifications to apparent distributions determined by sedimentation analysis as a function of the shape factor p and of the distribution of one of the main axes. In Figure 7 the results of a calculation for plates are given where Equation (51) was numerically integrated using the Gates–Gaudin–Schumann frequency distribution, Equation (52)

$$q_3(x_a) = \frac{m}{x_{max}} \left(\frac{x_a}{x_{max}}\right)^{m-1} \tag{52}$$

It can be seen that the distribution parameter m (slope of the distribution of x_a) is maintained in practice for the distributions of x_S and that with decreasing p the distributions shift to smaller particle sizes, x_S, by a nearly constant factor. For plates this factor is approximately $1.21 \times p^{1/2}$. This behavior means that it is possible to calculate a mean shape factor from a measured apparent size distribution $Q_3(x_S)$ (by means of sedimentation analysis) and another measured distribution of one main axis (e.g. $Q_3(x_a)$ by means of image analysis).

The principle shown is also applicable for other kinds of polydispersity (see Bernhardt[13]).

2.2.3 Brownian Motion

It is well known that the fluid molecules of the dispersion medium are subject to thermal motion whose kinetic energy is transferred to the suspended particles. The impact processes are of a stochastic nature; their amounts and directions do not compensate each other at the particle surface at any given time. This is why the particles themselves are subject to stochastic motion, the so-called Brownian motion, which is reflected both by shifts in the three spatial directions and rotation. The macroscopic appearance of this is described by the concepts of translation and rotation diffusion.

In this section, we shall attempt to assess the effects of translating diffusion taking place during sedimentation on the results of the incremental sedimentation analysis. The rotation diffusion will be neglected since we are also restricting ourselves to spherical particles for which the effects of this type of diffusion on the sedimentation movement can be neglected.[21]

In mathematical terms, the problem is equivalent to the solution of the well-known differential Equation (53)

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial h^2} - U\frac{\partial c}{\partial h} \tag{53}$$

with the diffusion coefficient, Equation (54)

$$D = \frac{kT}{3\pi\eta x} \tag{54}$$

where the Boltzmann constant $k = 1.38 \times 10^{-16}\,\mathrm{g\,cm\,s^{-2}\,K^{-1}}$ and c is the particle concentration at time t in depth h.

Solutions for different initial conditions have been found by Mason and Weaver[49] and later by Fürth[50,51] in the mid-1920s. New considerations were made using their results (see Bernhardt[13,31]). The equations for a vessel of finite dimensions (i.e. with a suspension level and with a bottom) are complicated and difficult to treat. Therefore, frequently the more simple case is found in the literature for an infinitely long vessel with a sharp borderline of particles at $t = 0$. Large differences between the two cases occur if the level of measurement is situated near the limitations (bottom and upper levels, respectively).[13] But if the measurement level is placed close to the middle of the vessel then the simple solution is sufficiently accurate. In this case the apparent distribution of a monodisperse system is given by, Equations (55–57)

$$Q_3(x_S) = \tfrac{1}{2} - \phi_0(z) \tag{55}$$

where

$$z = \frac{x^2 - x_S^2}{x}\; xh_M\frac{\pi}{12}\frac{\Delta\rho g}{kT}^{1/2} \tag{56}$$

$$\phi_0(z) = \frac{1}{\sqrt{2\pi}}\int_0^z \exp\left\{-\frac{\zeta^2}{2}\right\}\mathrm{d}\zeta \tag{57}$$

The larger the argument z, the smaller are the effects of the diffusion phenomena on the results of incremental sedimentation analysis, which means that a reduced influence occurs by:

- larger particle size x,
- larger sedimentation height h_M,
- higher acceleration g,
- higher density difference $\Delta\rho = \rho_s - \rho_m$,
- lower temperature T.

This is illustrated by two examples (see Figure 8).

Figure 8(a) demonstrates the extraordinary importance of the sedimentation path; in spite of a shorter measurement interval, measurements with small h_M lead to much

Figure 8 Apparent distributions of monodisperse particles caused by Brownian motion in the gravity field (quartz in water), according to Equation (57). (Reproduced from Bernhardt,[13] Copyright 1994, with kind permission from Kluwer Academic Publishers.)

wider apparent distributions than are found with a large h_M. For modern sedimentation analyzers which measure very narrow distributions in the gravity field, this is a decisive restriction in use. In contrast, working in the centrifugal field is much easier. According to Equation (57), an acceleration of $b = 100$ g constant over the sedimentation path produces the same apparent distribution as a one hundred times greater height h_M or a five times greater size x in the gravity field (see also Svedberg and Rinde[52]).

For polydisperse solids with a true frequency distribution $q_3(x) = dQ_3(x)/dx$ the total concentration of all particles at depth h_M and time $t(x_S)$ is the integral of the concentrations of the individual particle sizes weighted

Figure 9 Measuring errors caused by diffusion/Brownian motion, 1 – according to Chung and Hogg,[54] 2, 3 – according to Allen[55] with simultaneous decrease in height h_M by scanning. (Reproduced from Bernhardt,[13] Copyright 1994, with kind permission from Kluwer Academic Publishers.)

by the frequency distribution, Equation (58)

$$Q_3(x_S) = \int_0^{x_{max}} \left(\frac{1}{2} - \phi_0(z)\right) \quad q_3(x)\,dx \qquad (58)$$

In order to estimate the deviations existing between the true and the measured distribution, it has been repeatedly proposed that one of the known distribution functions for the frequency distribution be used and that Equation (58) be integrated with it.[53–55] Several of the results are presented in Figure 9.

For the true distribution $Q_3(x)$, logarithmic normal distributions of different median x_{50} were used: 1, $x_{50} = 0.14\,\mu$m; 2, $x_{50} = 0.5\,\mu$m; 3, $x_{50} = 1\,\mu$m. In the range $x < x_{50}$ the error represented $\Delta Q_3 = Q_3(x_S) - Q_3(x)$ is positive and negative and remains small. On the whole, it has to be said, that polydispersity strongly reduces the effect of diffusion. The reason for this is that there is a certain symmetric concentration distribution of the individual particle sizes, and therefore, because of the integration the effect is only remarkable in so far as the symmetry is incomplete. This also explains why shifts occur in both the fine and the coarse range.

From this point of view, incremental measurements in the gravitational field down to 0.1 µm and in the centrifugal field down to 0.01 µm are the limits down to which measurements of polydisperse solids can be performed with an admissible error.

Further details about the diffusion effect in cumulative suspension methods and in incremental line start methods are summarized by Bernhardt[13] and Mason and Weaver.[49]

2.2.4 Geometry of the Sedimentation Vessel

The influence of the vessel geometry is due to the fact that the particles sediment more slowly in the neighborhood

of the suspension boundaries (walls, bottom, lid) than at an infinite distance from them.

2.2.4.1 Influence of Walls According to several authors[56–59] Equation (59) holds for a sphere situated in a cylindrical sedimentation vessel near the wall:

$$\frac{U}{U_0} = 1 - \frac{9}{32}\frac{x}{l} \tag{59}$$

where U_0 is the undisturbed sedimentation velocity and l is the distance of the sphere center from the wall.

The same relationship was derived by Lorentz[60] for a sphere sedimenting in parallel to a plane wall. The most modern sedimentation devices are equipped with measuring cells which have two parallel walls a small distance apart (some millimeters). Therefore, the theory of Faxén [cited in Happel and Brenner[17]] for a sphere between two parallel walls is of particular interest. An useful approximation developed by Oseen [cited in Happel and Brenner[17]] for a random position of the sphere is given by Equation (60)

$$\frac{U}{U_0} = 1 - \frac{9}{32}\frac{x}{l_1}\frac{1}{1 - l_1/L} \tag{60}$$

where L is the distance between the walls and l_1 is the distance of the particle center from one wall.

The question arises how the influence of the wall affects the measured result of the sedimentation analysis. Figure 10 shows the change in sedimentation velocity over the relative distance from the wall. For monodisperse material subjected to an incremental method, the curves also characterize the position at which the solid concentration jumps from 0 to 1.

Figure 10 Change in the sedimentation velocity by the influence of the wall for different particle sizes and a wall distance of 0.5 cm.

This concentration distribution leads to an apparent distribution Equation (61):[13]

$$Q_3(x_S) = 1 - \left(1 - \frac{9}{8L}\frac{x^3}{x^2 - x_S^2}\right)^{1/2} \tag{61}$$

In the case of polydisperse materials, Equation (61) has to be integrated for all x. Taking into account that $c/c_0 = 1$ is already true for particles $x_P < x_M$ (see Bernhardt[13]) we obtain

$$Q_3(x_S) = 1 - \int_{x_P}^{x_{max}} \left(1 - \frac{9}{8L}\frac{x^3}{x^2 - x_S^2}\right)^{1/2} q_3(x)\,dx \tag{62}$$

The numerical integration of Equation (62) and the application of a Gates–Gaudin–Schumann distribution (Equation 52) leads to differences with respect to the true distribution, shown in Figure 11.

The difference $\Delta Q_3 = Q_3(x_S) - Q_3(x)$ usually reaches a measurement error of approx. 2% with sedimentation analyses only for narrow particle size distributions ($m \approx 2$), and even then only in the narrow and steep range close to the rear end of the distribution.

2.2.4.2 Influence of Horizontal Limitations Horizontal limitations of suspensions can be either closed/fixed (lid, bottom) or open (free surface). Theories comprising both cases were developed by Brenner, Wakiya and Faxén [cited in Happel and Brenner[17]]. For practical

Figure 11 Errors due to influence of wall (for polydisperse material, wall distance 0.5 cm). (Reproduced from Bernhardt,[13] Copyright 1994, with kind permission from Kluwer Academic Publishers.)

purposes ($x/h < 0.8$), the half-empirical approximations can be employed, Equations (63) and (64):
for a closed/fixed limitation:

$$\frac{U}{U_0} = 1 - 0.55\frac{x}{h} \tag{63}$$

for an open limitation (suspension level):

$$\frac{U}{U_0} = 1 - 0.375\frac{x}{h} \tag{64}$$

where h is the distance of the particle from the limitation.

The changes remain very small and can be neglected for practical purposes, because like other modern instruments no values of $x/h > 0.01$ are reached. The same is true for the apparent distribution measured by incremental analysis of a monodisperse material in a closed sedimentation vessel, Equation (65):

$$Q_3(x_S) = \frac{0.25x/h}{1 + 0.25x/h - x_S^2/x^2} \tag{65}$$

2.2.5 Other Parameters of Influence

2.2.5.1 Concentration of Solids For technical reasons, the sedimentation methods require suspensions, whose solids concentration must not fall below a certain minimum value. The influence on the sedimentation velocity is an extraordinarily complex problem essentially based on the following effects:

1. The density and viscosity of the suspension are greater than those of the pure liquid (not demonstrated here).
2. For reasons of continuity, the downward volume flow of solid particles is met by a liquid flow of the same magnitude (back flow).
3. In the vicinity of the sedimenting particle, the velocity field is disturbed leading to an increased exchange of momentum (cluster turbulence).
4. The drag force on the individual particle is reduced in the Stokes range by hydrodynamic interaction with neighboring particles.
5. By physicochemical interactions, the solvate sheath carried by the particle (change of effective particle density and suspension viscosity) and the coagulation during collisions (suspension stability) are influenced decisively.

Table 7 gives a survey of the necessary solids concentration for several sedimentation methods.

The relative particle distances h/x (h, the distance between the surfaces of the particles which are assumed to be spherical) were estimated by, Equation (66):

$$\frac{h}{x} = \left(\frac{0.68}{c_V}\right)^{1/3} - 1 \tag{66}$$

Table 7 Essential volume concentrations of solids and estimated particle distances of several sedimentation methods

Method	Essential solids concentration c_V (%)	Particle/particle distance h/x random arrangement	Particle/particle distance h_{12}/x median of distribution
Light-optical	0.005	22.9	11.0
Sedimentation balance	0.1	7.8	3.5
Pipette	0.5	4.1	1.7
X-ray absorption	3	1.8	0.3

However, the mean distance h is not a useful characteristic because in reality there is a distribution in the distances, and the smallest one is decisive for the suspension property. With solids concentrations c_V that are not too great, the number distribution of h_{12} (the distance between the surface of a particle and that of its nearest neighbor) is given by, Equation (67).[61,62]

$$Q_0\left(\frac{h_{12}}{x}\right) = 1 - \exp\left\{-8c_V\left[\left(\frac{h_{12}}{x} + 1\right)^3 - 1\right]\right\} \tag{67}$$

Some examples of the distribution are represented in Figure 12.

The median of this distribution is also given in Table 7. The very small distances below the median for larger solids concentration are the reason for most of the effects described in the following.

Figure 12 Number distribution of the distance h_{12}; parameter: volume concentration of solid.

Back Flow. Owing to the fluid flow counteracting the downward particle flow, the sedimentation velocity of particles of the same size reduced by the back flow velocity is, Equation (68)[63]

$$\frac{U}{U_0} = \frac{(1 - c_V)^2}{\eta/\eta_0} \tag{68}$$

where η_0 is the viscosity of the fluid without particles. As a result, the error in particle size $f_x = 1 - (U/U_0)^{1/2}$ has already reached approx. <7% in the concentration range $c_v < 3\%$.

Swarm Inhibition. Among all the numerous half-empirical and physically founded models describing the whole phenomenon of swarm inhibition (including back flow and swarm turbulence), only that proposed by Bauer and Thiele[64] will be mentioned here. For the case of a monodisperse solid, Equation (69) holds

$$\frac{U}{U_0} = (1 - c_V) \quad 1 + \frac{c_V}{(1 - c_V)^2} \times \quad 1 + \frac{1.05}{\sqrt{1 + (\pi/12c_V)^2} - 0.5} \Bigg\}^{-1} \tag{69}$$

Now, $f_x = 1 - (U/U_0)^{1/2}$ becomes <9% for $c_V < 3\%$. The influence is much stronger if the solid is polydisperse and if the analyzed particles are very small.

Hydrodynamic Interaction. The hydrodynamic interactions between two sedimenting spheres of the same size lead to a reduction in the drag force, for which a theory was developed by Happel and Brenner.[17]

The velocity ratio U_2/U is approximately given by Equation (70)

$$\frac{U_2}{U} = 1 + \frac{3}{8}\frac{x}{l}(1 + \cos^2\beta) = 1 + \frac{3}{8}\frac{1 + \cos^2\beta}{1 + h/x} \tag{70}$$

β is the angle between the sedimentation direction and the line connecting the sphere centers. According to Equation (70) the sedimentation velocity continuously increases with increasing solids concentration. Kaye and Boardman[65] and Johne,[66] however, have empirically found that this is true only up to a certain solids concentration, above which the swarm inhibition prevails. Johne's result, the average velocity of individual spheres related to their Stokes velocity, is shown in Figure 13.

Below $c_V = 10^{-4}$ the solids concentration is practically without influence on the particle movement. In the immediate vicinity of $c_V = 10^{-2}$, a velocity maximum forms which can be three times higher than the Stokes velocity. As shown by Koglin,[58] the phenomenon cannot be explained simply by the statistical arrangement of the particles and their hydrodynamic interaction plus swarm inhibition. In addition, the formation of complexes of particles (clusters), whose dimensions and sedimentation velocities grow with increasing sedimentation path and time, has to be assumed.[67] Furthermore, the size of these complexes is statistically distributed in the suspension so that the sedimentation velocity itself has a distribution. The mean value of this distribution (see Figure 13) strongly depends on both the particle size distribution and the particle shape distribution as well as on other physical parameters of the sedimenting solid.[58,68] The velocity maximum is lower, the wider the size distribution. Deviations from sphericity reduce the height of the maximum and simultaneously shift it towards lower solids concentrations.[1–12]

Figure 13 Empirical curve of the average sedimentation velocity of individual spheres in a suspension of monodisperse spheres. (Reproduced from Bernhardt,[13] Copyright 1994, with kind permission from Kluwer Academic Publishers.)

For light optical methods, sedimentation balances and usual pipette methods (with restrictions), the concentration of solids can normally be kept sufficiently low in practice to exclude the influence described. Other methods such as X-ray absorption reach the critical concentration range around $c_V = 0.01$ for various substances (silicates etc.). In this case, the measurement of narrowly classified material, for example, can yield a clear shift to coarser results in comparison to other methods.[13]

2.2.5.2 Convection Flows Convection flows occur whenever a suspension of higher density is situated beside or above a suspension of lower density. According to Koglin, Alex and Leschonski[1–12] the following are at least some of the reasons:

1. The sedimentation vessel does not have exactly vertical walls.

2. In the sedimentation vessel there are inserts (e.g. pipette or other bodies).
3. There are local temperature differences in the suspension caused by fast or inhomogeneous heating (e.g. solar heat radiation) or cooling (e.g. by evaporation at the suspension surface).

While the causes 1 and 2 can usually be overcome by improved design,[69] this is not so easy for cause 3. According to Rumpf[70] and Alex[71] a change of temperature of ± 1 K per analysis and 0.01 K min^{-1} should not be exceeded in a pipette device if the lower limit of measurement is 1 µm. It is difficult always to comply with the latter requirement even with good thermostats. Moreover, particularly in this field the commercially available measurement equipment very often does not meet these requirements.

Convection flows of a different type occur at the beginning of the analysis when a uniform distribution of the solid has to be achieved for suspension methods by stirring or shaking. The decay times observed with water were between 20 and 120 s dependent on the vessel geometry.

In line start methods, a suspension layer is positioned on top of a solid-free liquid at the beginning. When the solids concentration exceeds a certain value, density convection flows occur in the form of streaks, a phenomenon to which Alex et al.[1–12] have drawn to attention so vividly particularly in the case of centrifugal methods. The critical solids concentration at which this process begins is approx. 0.01 vol% according to investigations by Alex et al. This is an amount which is normally not sufficient to measure the mass proportions with satisfactory reliability (except light optical methods).

2.2.5.3 Hydrate Sheath For most particle systems it has to be assumed that a solvate (or in the special case of water, hydrate) sheath is formed, caused by the interaction between the electrically charged particle surface and the molecules of the liquid. This hydrate sheath is carried with the moving particle, with its thickness D_H depending on the equilibrium between the attraction forces and the flow forces. To estimate the influence of this phenomenon on particle motion, only the change in the effective particle density during sedimentation is taken into account. For spherical particles Equation (71) holds

$$\frac{\Delta\rho^*}{\Delta\rho} = \frac{x^3}{(x+2D_H)^3} = \left(\frac{1+2D_H}{x}\right)^{-3} \qquad (71)$$

Then, the error in the particle size is, Equation (72)

$$f_x = 1 - \left(\frac{\Delta\rho^*}{\Delta\rho}\right)^{1/2} = 1 - \left(\frac{1+2D_H}{x}\right)^{-3/2} \qquad (72)$$

The difficulty in such an estimation has to do with the fact that the exact density of the hydrate sheath ρ_H is not known. As a first approximation we have to assume that $\rho_H = \rho_m$.

For water a thickness of 3 nm equals approx. 10 molecular layers. Using this value it is evident that for particles >1 µm, the error in the particle size does not exceed 1%, and for particles > 0.2 µm does not exceed 5%. Owing to the lower density of the particles, the distribution curve $Q_3(x)$ is shifted towards greater fineness.

3 DISPERSION OF SOLIDS IN LIQUIDS

3.1 Introduction and Problems

For particle size analysis by sedimentation a suspension with a defined and constant dispersion state is an essential precondition. In many cases it is very difficult if not impossible to fulfil this precondition in a simple way, since the available information on the complex physicochemical conditions and their mutual interaction is not complete and can be extended only by extensive and partly empirical investigations. Furthermore, in many cases it is impossible to find a satisfactory answer to the question of the desirable dispersion state, which is dependent on the aim of measurement. Ideally, the following requirements would have to be met:

1. The solid particles exist in the suspension individually, i.e. free of agglomerates.
2. The dispersion state shall not be modified in any measurable way during the analysis.

Of course, the transition from separate particles to agglomerates is fluid for different solids, but even in spite of this, the analysis of real powder-type solids will always be at a greater or lesser distance from these ideal conditions.

Incomplete dispersion is often connected with a poor reproducibility of results, so that the decisive factor in sample preparation is to meet the above requirements as closely as possible and simultaneously to measure the state of the system investigated.[72]

If a dry powder is to be used for the preparation of a suspension for granulometric analysis, an agglomeration of the primary particles usually has to be expected dependent on the material properties and the conditions during manufacture and storage. The following binding mechanisms play a role:[73]

- binding by adhesion forces between the particles
- binding by wetting liquids of low viscosity
- binding by highly viscous liquids

- binding by solid bridges
- positive bridges.

Dispersion has the task of counteracting these forces by physicochemical and mechanical means to such a degree that the particles will eventually exist individually (i.e. agglomerate-free) and will not change this state in the course of the analysis. For this, certain basic mechanisms are required which can be reduced to the following three fundamental processes:

1. wetting of the solid particles by the liquid
2. desagglomeration of the particle agglomerates
3. stabilization of the suspension or prevention of renewed agglomeration.

The control of the wetting processes only allows the adhesion forces to be modified between the particles and the binding forces produced by liquids in the intermediate capillaries to be partially modified. The methods of desagglomeration should have an effect on all binding forces. Finally, most stabilization is achieved by modifying the interaction forces between the particles.

In spite of their extraordinarily wide range, the methods used to influence and control these processes can be reduced to the following tasks:

1. selection of a suitable liquid (suspending agent)
2. selection of the type and concentration of a suitable (interface active) aid (dispersant),
3. selection of the type and duration of mechanical preparation for dispersion.

In addition to its role in creating favorable conditions for wetting, desagglomeration and stabilization, the liquid medium has to meet several other requirements; these are (according to Irani and Callis[74] and Joglekar and Marathe[75]):

1. The solid must not dissolve or chemically be altered under the influence of the liquid, it must neither swell nor shrink.
2. Density and viscosity of the liquid have to be adapted to the solid density, maximum particle size and other parameters of the solid in such a way that measurement takes place at sedimentation velocities which are neither too high nor too low.
3. It has to be possible to render the liquid bubble-free.
4. The liquid should have a vapor pressure as low as possible.
5. The liquid has to be nontoxic, inexpensive and easily available.

The fundamentals of the mentioned physicochemical and physical problems (wetting, particle/particle attraction and repulsion etc.) cannot be treated here in detail. For further information the reader may refer to some well-known monographs[24,76–81] and overviews.[13,82–84]

3.2 Stabilization of Suspensions

In many cases the so-called DLVO theory (Deryaguin, Landau, Verwey and Overbeck) is a useful tool for solving dispersion problems, particularly the stabilization of suspensions. The total interaction energy between two solid particles can be written as the sum of the electrostatic repulsion, the van der Waals attraction and the steric repulsion, Equation (73)

$$V(h) = V_{el}(h) + V_A(h) + V_{Ster} \tag{73}$$

The theoretical fundamentals were developed by Deryaguin, Landau, Verwey and Overbeck; originally, the theory referred only to the combination of electrostatic and van der Waals interaction. Under these conditions they found a principal curve of $V(h)$, represented in Figure 14.

When two particles approach each other from a large distance, they proceed through the range of relatively small attraction energies called secondary minima. If these are greater than the collision energy of the particles,

Figure 14 Total interaction energy between two particles (principal scheme) according to DLVO theory. (Reproduced from Bernhardt,[13] Copyright 1994, with kind permission from Kluwer Academic Publishers.)

agglomeration takes place then. Since it is impossible to destroy the agglomerates mechanically during sedimentation analysis, conditions have to be found under which the secondary minimum is as small as possible or disappears altogether. This is the case for high interfacial potentials or (preferably) large thicknesses of the double layer and small van der Waals attraction energies.

In these cases, the repulsion energy barrier is so high that agglomeration is possible only for very high-energy collisions of the particles. In this case, the particles adhere to each other in the primary minimum, forming relatively stable agglomerates. However, if the maximum repulsion energy is always greater than the collision energy, the suspension will be stable.

The opposite case, that is, the complete absence of repulsion energies (e.g. for small potentials and small double layer thickness) leads to agglomeration in every case of collision (fast coagulation).

Therefore, in addition to wetting and desagglomeration, the stability of the suspension over the time required for analysis is a decisive problem in the granulometric analysis of suspended particles.

Now, it has to be asked which changes in the number of particles caused by coagulation during sedimentation are within the error range of the analysis data. The results of Bernhardt[85] provide some information on this. Thus, it is fully possible for slowly coagulating systems to meet sedimentation conditions which limit the resulting error. An effective way is the use of minimum solids concentrations or sedimentation times that are as short as possible (low-sedimentation heights).

Modern devices sometimes have sedimentation heights under 0.1 mm; it can be expected that these can be used even for very unfavorable stability conditions, provided, of course, that the time for the other stages of suspension preparation can be kept short.

To give the reader a better overview, some conclusions will be made on the basis of the above statements (see also Bernhardt[13]).

Dispersion in liquids has the following objectives:

1. Spontaneous wetting as complete as possible
   - General aim:
     - high-wetting energy,
     - low-contact angle;
   - Solution:
     - low-interfacial tension liquid/gas by wetting agents,
     - low-interfacial tension solid/liquid by hydrophilizing agents.
2. High electrostatic repulsion energy
   - General aim:
     - high-interfacial potential,
     - great thickness of double layer at low-ionic strength;
   - Solution:
     - polar liquids (high-dielectric constant),
     - use of potential-controlling ions,
     - use of polyelectrolytes for adsorption in the Stern layer.
3. Low van der Waals attraction energy
   - General aim:
     - small difference in Hamaker constants of solid and liquid,
     - large particle distance.
   - Solution:
     - selection of suitable liquids,
     - masking of solid surface by adsorption layer with Hamaker constant similar to that of liquid,
     - adsorption of big molecules or small solid particles for steric repulsion,
     - low-solids concentration.
4. High-repulsion barrier and low-secondary energy minimum
   - same as 2 and 3.
5. Low probability of agglomeration at collision
   - General aim:
     - same as 2 and 3,
     - low-kinetic energy of particles;
   - Solution:
     - same as 2 and 3,
     - high viscosity of the fluid.
6. Low collision probability
   - General aim and solution:
     - low kinetic energy,
     - low solids concentration,
     - short duration of measurement.

It is obvious that the above recommendations are not a recipe for all cases; in many cases, they are not compatible with each other (this has not been described in detail), and they do not guarantee successful dispersion.

The overview shows that good dispersion depends on a very large complex of influencing factors acting together as well as against each other. For many solids, particularly if they are contaminated or heterogeneous, an empirical approach cannot be avoided. There are many examples of this in the literature. Appendix 1 gives an overview of liquids and dispersion aids for sedimentation analysis on the basis of a previous work.[13,84]

Of course, all these data are just recommendations which do not exempt the user from the obligation of informing him or herself on the effectiveness of dispersion techniques, and to test further materials and techniques.

3.3 Desagglomeration Methods

Mechanical processes have to be used in most cases of suspension pretreatment, to support or initiate the physicochemical phenomena or to destroy the agglomerates originally present in the system to allow stabilization measures to be come effective. The most important methods will be described briefly.

3.3.1 Dry Sieving

The dry powder is sieved through a test sieve of suitable mesh (e.g. 40 μm) using a brush or similar mechanical aid. The coarse agglomerates are destroyed by this treatment to a degree sufficient for the successful application of other methods (such as ultrasound) for complete desagglomeration. At the same time, the maximum particle size of the system to be analyzed is reduced to a value that can still be reliably measured. This method is preferable in comparison with comminution in a mortar or between two plates,[74] because the latter is susceptible to the danger of destroying large primary particles.

3.3.2 Treatment in Plastic State

In the method described by Allen[16] and Irani and Callis,[74] the powder sample is put on a glass plate or a very flat vessel after which a small amount of water is added, producing a plastic mixture. This is kneaded for some minutes with a suitable spatula. Then, a proper suspension is produced from this material. This method is used if coarser agglomerates must be destroyed with caution or if the material cannot be wetted with ease.

3.3.3 Deaeration of the Solid

For a very fine and/or barely wettable solid, it often makes sense to remove the included air. The following methods are recommended for the production of a sufficiently deaerated suspension:

- addition of liquid to powder in vacuum
- stirring of suspension in vacuum
- boiling of suspension
- treatment of suspension in a laboratory ball mill (without pebbles).

These measures also destroy agglomerates.

3.3.4 Treatment in a Turbulent Shear Field

The simple manual or machine shaking of a suspension in a closed vessel has only a slight desagglomerating effect, because the agglomerate strengths exceed the stress during shaking in most cases. Another possible treatment is stirring. Its use is recommended primarily for cases where wetting is difficult; however, it also contributes to agglomerate destruction to a limited extent.

In this context, the investigations by Nagel and Kürten[86] are of special interest; here, the agglomerate strengths estimated by Rumpf and Herrmann[73] are compared with stress calculated for the shear field. For possible technical values of power dissipation density between 10^3 and 10^4 kW m^{-3}, only particle agglomerates >10 μm can be destroyed if there is only van der Waals binding; in the case of sinter bridges the particles must be >100 μm. This was confirmed experimentally[86] and is in agreement with practical experience.[87]

Finally, another effective method of desagglomeration is the turbulent flow of an annular shear slot. The advantage of this method is the possibility of estimating the forces attacking the particle agglomerates in good approximation.[88,89]

3.3.5 Ultrasonic Treatment

In view of the limited desagglomeration by stirring for small agglomerates, treatment in the ultrasonic field is of special importance for suspension preparation for granulometric analysis. The mechanism of the processes involved has not yet been completely clarified; however, there is general agreement that cavitation is a prerequisite for desagglomeration.

In the ultrasonic field, cavitation is provoked by tensile stresses produced by the acoustical pressure. At first, small cavities (cavitation bubbles) form in the liquid when the so-called cavitation threshold is reached, which grow to a maximum size under oscillations and then collapse very rapidly. In real liquids containing solid particles the cavitation produces complex changes in diverse physical properties which lead to the damping of the ultrasound in the cavitation zone (see also Šutilov[90]) and, thus, a reduction of the cavitation

pressure. With increasing sound frequency, the sound energy producing the necessary cavitation increases. For dispersion purposes, frequencies between 20 and 40 Hz for which the necessary acoustical pressures are guaranteed as well are generally used. An increase in the external pressure and liquid temperature improves the effectiveness of ultrasound.[87,90] It is often indicated that, unlike other mechanical destruction methods, ultrasound has an eroding effect,[91] that is, the primary particles are removed from the agglomerates starting at the surface.

Practical ultrasonic treatment of a suspension for granulometric analysis is usually carried out using two principles:

Principle (a) uses a commercial ultrasound washing device. The suspension vessel is put or suspended in a water bath and irradiated by an ultrasound source fastened to the bottom of the bath. Because of the low-ultrasound intensity, the treatment usually requires a long time to attain the required state of dispersion. In spite of this, the method is widely used in view of its simplicity.[13]

In principle (b), the suspension in the vessel is irradiated directly by a sonotrode. Modern commercial devices usually have a fixed frequency; their intensity can be selected (specific power up to approx. 500 W cm^{-2}). This allows the duration of treatment to be reduced to a few minutes. Intensities between 100 and 200 W cm^{-2} are usually sufficient.

The dispersing effect of ultrasound decreases with increasing solids concentration, it can be increased in the presence of surfactants. In the most unfavorable cases, even coagulation can occur.[92–94]

In some studies the combination of ultrasound with another type of mechanical pretreatment reduces the essential time or provides a higher degree of dispersion.[45,95] Davies et al.[87] found that ultrasound is most effective for the destruction of small agglomerates while high-speed stirring is best for destroying large agglomerates.

A question always asked in the framework of such investigations is whether ultrasonic treatment destroys the primary particles forming the agglomerates. It is known[91] that ultrasound can destroy structures such as the solid bridges between the particles. Davies et al.[87] observed changes in the surface roughness of particles $> 5\,\mu m$.

According to Gärtner,[96] particle destruction at the weak connections also has to be expected for precipitation products whose particles consist of several primary crystallites. The newly formed primary crystallites, however, do not show a tendency towards further decomposition.

A remarkable reduction in the particle size was observed for solids with a pronounced anisotropy of cleavability; examples are chrysotile asbestos[97] or talcum.[47] Thus, it can be assumed that most substances (with the exception of those with extreme properties) are not comminuted by ultrasound.

3.4 Characterization of the Dispersion State and the Dispersion Capacity

If the task is to produce a suspension of maximum dispersion for a particle size analysis, it must first be possible to characterize the current degree of dispersion. At the same time, information is needed on possible changes in the physicochemical and mechanical methods with the aim of improving the current degree of dispersion. For this reason, apart from methods for the characterization of the dispersion degree this section will include methods in which the measured parameter has a connection with the dispersion capacity of the solid and from which further information on dispersion measures can be derived (liquid, dispersion aid, parameters of mechanical treatment).

3.4.1 Measurement of Wettability

For the measurement of the wettability the following methods are known:

- measurement of wetting heat
- measurement of adsorption isotherms
- measurement of the contact angle.

Their application to powder-type substances presupposes the availability of the necessary measurement equipment. On the other hand, extensive wetting problems are instantly noticed as an obstacle to suspension preparation that cannot be circumvented. In the case of an insufficient degree of dispersion, insufficient wetting should always be looked upon as a possible reason.

3.4.2 Rheologic Tests

Flow characteristics and dispersion degree are connected in a way that in most cases is specific to the given material. In general, the flowability is best at maximum dispersion. The exact determination of the rheologic characteristics requires measurement equipment (such as rotation viscosimeters) which is not always available. Therefore, such measurements will be done only in special cases; Joglekar and Marathe[75] recommend them for sedimentation analysis of clay suspensions.

In the case of a fast method also mentioned by Joglekar and Marathe[75] a small amount of suspension is placed on an inclined glass plate. Well-dispersed systems form a smooth uniform layer when flowing down, whereas flocculated suspensions produce a layer in stripes with a heterogeneous lumpy appearance.

Good characterization of the material behavior involves determination of the smear point (beginning of plastic behavior) and the flow point which can be done by relatively simple means.[16,74,75] For this, the dry powder is put into a small vessel (a few grams), and the liquid is added slowly from a burette while the powder is stirred with a spatula or glass rod. The amount of liquid consumed up to the smear point and the flow point is read. The smaller the difference between these two values, the better the dispersion capacity.

3.4.3 Microscopic Analysis

A simple microscopic assessment normally provides little more than qualitative information on the type of liquid and additive and the effect of the mechanical pretreatment.[74,75] A droplet from the ready suspension is brought to the microscope slide. This provides an immediate impression of the analyzed system, its dispersion state and its tendency towards coagulation.

3.4.4 Sedimentation Test

Sedimentation tests in suitable standard laboratory vessels (test tubes, small gas jars) provide a simple means of assessing the dispersion state prior to the proper analysis.[74,75] The suspension is prepared with the same solids concentration as for the analysis; only the type and concentration of the dispersion aid is normally varied. All vessels are installed for the observation of the sedimentation process after uniform pretreatment of the suspension. Good dispersion is reflected by stronger turbidity after a certain time. Even small differences can be recognized by comparison with the neighboring vessels.

After a sufficient time it is possible to determine the volume of solids sedimented on the bottom of the suspension vessel. This sediment volume is smaller, the higher the degree of dispersion. Agglomerated systems form loose sediments with a high content of liquid equivalent to a large sediment volume.

For example a silicon nitride suspension (see Figure 15) shows the dependence of the sediment volume V_S on the pH-value of the suspension compared with electrophoretically determined ζ-potentials. As expected, high ζ-potentials lead to small sediment volumes and low ζ-potentials lead to high sediment volumes. Therefore, granulometric analysis without problems is expected either for high or low pH values, since these are equivalent to maximum desagglomeration and maximum suspension stability. For a further improvement of this method see Hirosue et al.[98]

Figure 15 Sediment volume and ζ-potential of Si_3N_4 suspensions. (Reproduced from Bernhardt,[13] Copyright 1994, with kind permission from Kluwer Academic Publishers.)

3.4.5 Photometric Measurement

According to several authors,[16,45,75,92,95,99] photometric turbidity measurement is carried out dependent on time on a suspension kept in motion (without sedimentation) and with simultaneous mechanical treatment (ultrasound, stirring) and variation of the type and concentration of the dispersion aid. Koglin[95] recommends an optical small-angle scheme measuring the attenuation of white light traversing the suspension in a forward direction. If the Lambert–Beer law is valid he proposed that the agglomeration degree β of a suspension be defined as follows, Equation (74):

$$\beta = 1 - \frac{\ln T}{\ln T_{\min}} = \frac{\ln(I_{\min}/I)}{\ln(I_{\min}/I_{\infty})} \qquad (74)$$

where I is the light intensity, I_{∞} is I for a solid free liquid, $I_{\min}$ is I for an agglomerated system.

For the interpretation of the effect of measurement, the fact that both the particle size distribution and the value of the extinction function $K(x)$ (see section 4.2.1) change must be taken into account. Koglin[95] therefore restricts the use of the method to particles $x > 1\,\mu m$. However, his investigations have shown that the influence of all means of dispersion are very well reflected, and procedures for the further treatment of the suspension can be selected very well.

For very high solids concentrations ($c_V > 1\%$) it is possible that measurable transmissions are achieved only for very thin cuvets. In this case, however, the scattered light intensity occurring under a certain angle can be measured and its changes can be followed. This can be done easily for some commercial types of equipment.

Another version of this method is the approach described by Joglekar and Marathe[75] and Süß and Hantke[92] according to which the photoextinction method is employed for surface determination. By comparison with surface values determined by other methods, conclusions are made with respect to the degree of dispersion.

3.4.6 Zeta Potential Measurement

A zeta potential measurement provides information on the charging state at the solid/liquid phase boundary. If the ζ-potential and its dependence on pH or other charge generating ions are known then in most cases it is possible to find conditions with maximum repulsion energies between the particles. The first application of ζ-potential measurements for the purposes of particle size analysis is described by Bernhardt.[85]

Experimental determination of the ζ-potential requires special measurement equipment which cannot be described here in detail (see Hiemenz[77] and Stauff[24]). Comprehensive measurements of a wide range of materials are documented by Hunter[78] and Ney[79] which are available if needed. In such a case, however, it appears to make sense to analyze the dispersion conditions of the material system in question at least on the basis of a second independent quantity (see also Figure 15).

3.4.7 Particle Size Analysis

When investigating the influence of the degree of agglomeration on the granulometric result it is recommended that the granulometric method itself be used for the preliminary assessment and to change the conditions of pretreatment until the results of measurement remain constant. However, this requires sufficiently fast measurement, which only modern automatic devices are capable of in sedimentation analysis. On the other hand, it is of great advantage to have available the complete particle size distribution for a comprehensive assessment of the agglomeration state.

In the literature there are two main characteristics for this:

1. degree of agglomeration α (=1 for complete agglomeration, =0 for complete dispersion)
2. degree of dispersion/desagglomeration β (=1 for complete desagglomeration, =0 for complete agglomeration).

The essential problem of all the different degrees of agglomeration is that the extreme points (0 and 1) are unknown. Instead we have to use the state in which we start the dispersion experiment or in which we finish it. Table 8 gives some examples of definitions for α and β, in which only ''complete dispersion'' is used (characterized by the primary particle).

Which characteristic is suitable for a certain purpose must be decided by the user in each case.

3.4.8 Comparison of Methods for Dispersion Control

Table 9 gives an overview of all the above statements about the suitability of the described methods for dispersion control. It must not be forgotten that the classification as suitable, conditional or barely suitable and not suitable is subjective and may depend on the accuracy of the information required.

Nonetheless, the overview provides the correct impression that in the normal case only a few methods are suitable for the solution of all four problems of suspension

Table 8 Degrees of desagglomeration and agglomeration

Basic characteristic	Degree of desagglomeration β	Degree of agglomeration α	Ref.
Median x_{50}	$\frac{x_{50,\mathrm{PP}}}{x_{50}}$		100
Mean particle size $x_\mathrm{m} = M_{1,3}$	$\frac{M_{1,3,\mathrm{PP}}}{M_{1,3}}$		
Second moment $M_{2,3}$	$\frac{M_{2,3,\mathrm{PP}}}{M_{2,3}}$		
Third moment $M_{3,3}$	$\frac{M_{3,3,\mathrm{PP}}}{M_{3,3}}$		101
Specific surface area $S_V = 6\,M_{-1,3}$	$\frac{M_{-1,3,\mathrm{PP}}}{M_{-1,3}}$		101, 95
Specific particle number by volume $M_{-3,3} = \frac{1}{M_{3,0}}$		$1 - \frac{M_{-3,3,\mathrm{PP}}}{M_{-3,3}}$	102
Arithmetic mean volume $M_{3,0}$ (third moment of number distribution)		$1 - \frac{M_{3,0,\mathrm{PP}}}{M_{3,0}}$	102
Standard deviation $s = ({}_\mathrm{m}M_{2,3})^{1/2}$ (second moment related to x_m)	$\frac{s_\mathrm{PP}}{s}$		13

$M_{k,r} = \int_0^\infty x^k q_r(x)\,\mathrm{d}x$; ${}_\mathrm{m}M_{k,r} = \int_0^\infty (x - x_\mathrm{m})^k q_r(x)\,\mathrm{d}x$; PP = primary particle.

Table 9 Methods of dispersion control

Method	Determination of			
	Type of liquid	Type of dispersant	Concentration of dispersant	Type and duration of mechanical treatment
Wettability	+	+	(+)	−
Rheologic test	+	+	(+)	−
Microscopic assessment	+	+	(+)	(+)
Sedimentation test	(+)	+	+	+
Photometric measurement	+	+	+	+
Zeta potential measurement	(+)	+	+	−
Particle size analysis	+	+	+	+

+ suitable, (+) conditional or barely suitable, − not suitable.

preparation and that there are only a few methods that allow characterization of the type and duration of mechanical pretreatment.

In conclusion, it follows that no absolute rules can be given for the use of the methods and that it makes sense to consider a combination of several methods on the basis of an assessment of costs and desired effects.

4 SEDIMENTATION METHODS

4.1 Brief Historical View

The development of sedimentation methods began with the soil analyses which have been extensively performed since the middle of the 19th century in which fractions of a certain fineness had to be determined. Because the sample material was elutriated in water, this was called elutriation analysis (Geßner, 1931[103]), a name which was used for most diverse methods for a long time.

A further line of development originates from colloid chemistry which developed rapidly at the beginning of the 20th century (Ostwald 1911[104] and von Hahn 1928[105]).

Apart from appropriate elutriation methods, cumulative methods in all their versions played a decisive role up to the first third of the 20th century. The application of Stokes' equation to sedimentation analysis was a decisive development at that time.

Decanting was abandoned at that time, and various automation or continuous methods of measurement were introduced (sedimentation balance according to Odén (1915);[106] pressure difference method according to Wiegner (1918)[107]). Centrifuges were first used around 1923 by Svedberg and Nichols[108] leading to both time reduction and an extension in the range of the finer fractions.

In the decade between 1920 and 1930, incremental (pipette) methods were invented almost simultaneously and independently by Robinson (1922),[109] Jennings et al.,[110] Krauss (1923),[111] Köhn (1928)[112] and, finally, Andreasen (1928).[113] Other incremental methods were those using areometers (Bouyoucos (1927)[114]) and later diving apparatus (Berg (1941)[115]).

After World War II, incremental methods with contact-free measurement of reasonable quantities by the attenuation of light or γ-radiation were used, and centrifuges were employed to this end. Only this allowed a drastic reduction of the sedimentation height down to fractions of 1 mm which also decreased the time requirements, so that sedimentation analysis remained an alternative and, in many cases, an indispensable granulometric method.

4.2 Gravitational Methods

4.2.1 Incremental Suspension Methods

4.2.1.1 Principle and Fundamentals For this measurement principle, there is a homogeneously mixed suspension at the beginning of the analysis ($t = 0$) so that the overall concentration c_0 prevails in every part of the sedimentation vessel. In Figure 16(a) the initial situation is represented so that the individual particle sizes are arranged beside each other.

After time $t > 0$, there will be a state which is described by Figure 16(b). One portion of the particles has sedimented on the bottom – more large ones than small ones in view of the former's higher sedimentation velocity. Thus, the upper concentration limits of the particles still sedimenting are at different heights in the sedimentation vessel in the order of their size. Size x has only just reached height h. Here, in the ideal case we measure the solids concentration $c(h, t)$ in a differential

Figure 16 Principle of incremental suspension methods. (a) $t = 0$, (b) $t > 0$.

thin layer after time t. For this, Equation (75) evidently holds

$$c(h,t) = c_0 \int_0^{x_t} q_3(x)\,\mathrm{d}x \tag{75}$$

from which follows Equation (76)

$$Q_3(x_t) = \frac{c(h,t)}{c_0} \tag{76}$$

This is the fundamental relationship on which the method is based.

Deviations from the ideal case were described in section 2.2 as far as they influence the settling velocity. Moreover two further problems appear:

1. the finite extension of the measuring gap
2. the heterogeneity of the solid material.

The simple Equation (76) is valid only if the solids concentration is measured as a function of time in a measuring plane. In practice, however, there is always a measuring volume, since both the entrance slit and the exit slit of the measuring radiation have a finite extension Δh (see also Figures 4 and 16). The apparent distribution of a monodisperse material can be calculated by Equation (77):[13]

$$Q_3(x_S) = \frac{1}{2} - \frac{h_M}{\Delta h}\left(\frac{x^2}{x_S^2} - 1\right. \tag{77}$$

and those of polydisperse material by Equation (78)

$$Q_3(x_S) = \int_{x_{t,\min}}^{x_{t,\max}} \frac{1}{2} - \frac{h_M}{\Delta h}\left(\frac{x^2}{x_S^2} - 1\right. \quad q_3(x)\,\mathrm{d}x + \int_0^{x_{t,\min}} q_3(x)\,\mathrm{d}x \tag{78}$$

with the integration limits: $x_{t,\max} = x_S(1 + \Delta h/2)^{1/2}$ and $x_{t,\min} = x_S(1 - \Delta h/2)^{1/2}$.

Using a Gates–Gaudin–Schumann distribution for $q_3(x)$ (Equation 52) it is possible to integrate Equation (78) analytically and calculate the differences between the true distribution and the apparent one.[13] In Figure 17 some examples of the error, Equation (79)

$$f(x_S) = \frac{Q_3(x) - Q_3(x_S)}{Q_3(x)} \text{ in \%} \tag{79}$$

are represented for different distribution parameters m.

The error attains values considerably greater than 1% only for very narrow distributions ($m \geq 3$), and even this only if $\Delta h/h_M$ is close to 1. Usually, $\Delta h/h_M = 0.2$ is not exceeded even by modern sedimentation devices. In this case the error can be neglected as a rule. The same is valid for pipette analysis, where a sink flow occurs at the pipette tip.[1–12]

Figure 17 Influence of the measuring gap width on the measured results. (Reproduced from Bernhardt,[13] Copyright 1994, with kind permission from Kluwer Academic Publishers.)

Further, it is assumed that the solid is a uniform system so that two particles differ only in size and no other property is relevant for measurement. This is not always so in practice. Frequently, the system consists of two or more components which may differ in some of the following properties affecting the sedimentation analysis:

1. particle size distribution $Q(x)$
2. particle shape distribution $Q(\xi)$
3. density ρ_s of the solid
4. refractive index m of the solid
5. mass attenuation coefficient μ of the solid.

Bernhardt[116] has investigated the problems resulting for incremental suspension methods. He found that a distinction must be made between properties affecting the sedimentation velocity and thus the particle sizes present on measurement level (2 and 3) and properties affecting quantity measurement (4 and 5).

The difference between components with respect to particle size distribution is insignificant and they do not produce incorrect measurements. In practice, however, components normally differ in all three properties 1 to 3.

For two-component systems in which the components with mass fractions p_1 and p_2 differ only in size distribution ($Q_{3,1}(x)$ and $Q_{3,2}(x)$) and solid density (ρ_1 and ρ_2), Equation (80) holds

$$\Delta Q_3 = Q_{3,\mathrm{mea}}(x) - Q_{3,\mathrm{act}}(x) = p_1[Q_{3,1}(x_\mathrm{M} f_1) - Q_{3,1}(x_\mathrm{M})] + p_2[Q_{3,2}(x_\mathrm{M} f_2) - Q_{3,2}(x_\mathrm{M})] \quad (80)$$

where x_M is the particle size, calculated using the mean solid density, $Q_{3,\mathrm{mea}}(x)$ is the measured (apparent) particle size distribution, $Q_{3,\mathrm{act}}(x)$ is actual particle size distribution and, Equation (81)

$$f_1 = \left[\frac{\rho_1\rho_2 - \rho_\mathrm{m}(\rho_1 p_2 + \rho_2 p_1)}{(\rho_1 - \rho_\mathrm{m})(\rho_1 p_2 + \rho_2 p_1)}\right]^{1/2}$$
$$f_2 = \left[\frac{\rho_1\rho_2 - \rho_\mathrm{m}(\rho_1 p_2 + \rho_2 p_1)}{(\rho_2 - \rho_\mathrm{m})(\rho_1 p_2 + \rho_2 p_1)}\right]^{1/2} \quad (81)$$

In rough approximation, Equation (82)

$$\Delta Q_3 \approx p_1(f_1 - 1)x_\mathrm{M}[q_{3,1}(x_\mathrm{M}) - q_{3,2}(x_\mathrm{M})] \quad (82)$$

where $q_{3,1}(x_\mathrm{M})$, $q_{3,2}(x_\mathrm{M})$ are the frequency distributions of the two components at x_M.

An analysis of this relationship shows:[116]

- Because the product $p_1(f_1 - 1)$ assumes an extreme value in the vicinity of $p_2 = 0.5$, large errors in Q_3 have to be expected here; the extreme value itself is determined by the density difference of the components.
- The error in Q_3 furthermore depends on the particle size x and the difference of the frequency distributions of the two components at this position.

It is mostly the latter factor which makes the error relatively small even for large density differences. The examples of mixtures of SiO_2 ($\rho_1 = 2.65\,\mathrm{g\,cm^{-3}}$) and Fe_2O_3 ($\rho_2 = 5.55\,\mathrm{g\,cm^{-2}}$) calculated by Bernhardt[116] have errors $\Delta Q_3 < 3\%$.

4.2.1.2 Gravimetric Pipette Methods In pipette analysis, the solids concentration at the measurement level (depth h) is determined by taking a sample of volume V (after time t) and subsequently determining the solid mass m by weighing (after drying). Then, Equation (83)

$$Q_3(x) = \frac{c(h,t)}{c_0} = \frac{m(t)}{m_0}\frac{V_0}{V(t)} \quad (83)$$

Pipette methods can be subdivided into the following groups:

- methods introducing the pipette from the top
  - pipette with fixed immersion depth
  - pipette with variable immersion depth
- methods with the pipette introduced from below
- methods with lateral introduction of the pipette.

Figure 18 Pipette devices with pipette introduced from the top. (Reproduced from Bernhardt,[13] Copyright 1994, with kind permission from Kluwer Academic Publishers.)

Figure 18 shows some examples of the methods involving introducing the pipette from the top. Figure 18(a) reflects the arrangement proposed by Robinson[109] as early as 1922 in which normal laboratory devices are used as sedimentation vessel (1) and pipette (2). After each sampling, the pipette had to be removed from the suspension and then had to be reintroduced. This disadvantage was overcome by a development by Andreasen[113] whose improved version[1–12] is represented in Figure 18(b). Between pipette tip (2) and sample vessel (3) a special two-way stopcock (4) is installed allowing the transfer of the sample volume ($10\,\mathrm{cm^3}$) to an evaporating and

weighing pan. Later developments avoided pipettes which were open at the tip and these were replaced by closed pipettes with lateral suction openings or annular slit-type arrangements.

Error analyses of the scheme in Figure 18(b) were done by Rumpf,[70] Kast[69] and especially Leschonski[1–12] on the basis of which the device in Figure 18(c) was developed. The pipette (2) now extends to the bottom of the sedimentation vessel (to exclude density convection flows) and has four lateral openings. To avoid falsification of the solids concentration of the following sample by the suspension residue between suction openings and stopcock (4), an equal preliminary volume is removed by means of the pipette element (5) and rejected. To avoid the necessity of slowing down the process in the case of suction close to the pipette marking or even to have to send back excess suspension to the vessel, a calibrated scale enabling the drawn volume to be read is attached to the upper end of the pipette.

A detailed description of the entire procedure (sample preparation, thermostatting, time measurement, weighing etc.) was given by Alex.[71] Rationalization measures such as automatic suction are recommended by Alex.[71] Nevertheless, pipette analysis with fixed immersion depth does not have the same importance today that it had in the decades between 1930 and 1970, the main reason being the excessively long analysis time.

In early work it was tried to limit the required time by a reduction in sedimentation height; Krauss[111] used this principle in the system he proposed in 1923. Unlike the pipette arrangement of Robinson,[109] three tubes with adjustable height, sealed bottom and lateral suction openings were used, and the suspension samples were transferred into a weighing vessel. Köhn[112] and Andreasen[113] again reduced this method to just one pipette and introduced improvements in handling, so that this principle eventually was further developed to a standard technique. A further simple system using this principle but not including guiding of the pipette by an external structure was proposed by Börner (see Figure 18d). Here, a pipette with adjustable height (2) is guided by a gear (6) consisting of rubber rolls which can be actuated by the handwheel (7) [cited by Bernhardt[13]].

Many fewer versions are known of systems which use a pipette introduced into the sedimentation vessel from below. These have the decisive advantage that the suspension sample is taken spontaneously so that no convection flows can form at the pipette tip. The method originally developed by Jennings et al.[110] does not include height reduction during analysis. Later, Dallendörfer and Langhammer,[117] Bernhardt and Lippek[118] and Zecha[119] used this principle again with the aim of reducing the sedimentation height during the analysis. As their investigations have shown, it is possible to work with heights down to 20 mm.

Sedimentation systems with a lateral pipette are mentioned here only for completeness sake; the systems developed by Esenwein, Berg and Stairmand [cited in Bernhardt[13] and Berg[53]] were only of limited or local importance.

4.2.1.3 Methods of Density Measurement The fundamental equation for the application of density measurement for incremental sedimentation analyses is given by Equation (84)

$$Q_3(x) = \frac{\varphi(h, t) - \rho_m}{\varphi_0 - \rho_m} \tag{84}$$

where the suspension density $\varphi = c_V(\rho_s - \rho_m)$.

Areometer Method. Bouyoucos[114] was the first to report on the measurement of the suspension density $\varphi(h, t)$ by means of areometers. It was a fast method much used particularly for soil analysis between 1930 and 1960.[74,120–122]

Measurement is performed in such a way that a suitable areometer is introduced into the suspension at certain intervals, and the density is read dependent on time. According to Rumpf[70] the method is cumulative in the strict sense; however, there are fundamental obstacles to an evaluation in this sense. This is why since Casagrande[123] the approach has been simplified by the concept of the areometer indicating the mean density at the depth of the center of the areometer head.

The method has grave disadvantages [see Rumpf,[70] Conley[124] and Allen[16]].

Diver Method. To overcome certain disadvantages of the areometer method, Berg[115] used miniature areometers without a shaft (divers) of accurately staggered density that remained in the sedimentation vessel during analysis. Such a body is always in the concentration range equivalent to its density. The measurement requires a certain number of divers with carefully adjusted density values. The depth of the diver is usually determined by means of a magnet drawing the divers to the glass wall of the sedimentation vessel. There are also some other designs.[16,122]

4.2.1.4 Photoelectric Methods

Fundamentals. The photoelectric methods make use of the fact that a light beam of intensity I_E is attenuated to intensity I_A when crossing a suspension. The attenuation law (Lambert–Beer law after its discoverers) is, Equation (85)

$$\ln T = \ln\left(\frac{I_A}{I_E}\right. = -A_V c_V L \tag{85}$$

A_V is the so-called scattering section related to particle volume ($=3K(x)/2x$) so that, Equation (86)

$$\ln \frac{I_A}{I_E} = \frac{3}{2}\frac{K(x)}{x} c_V L \tag{86}$$

where $K(x)$ is the extinction function. If the trans-illuminated suspension contains a polydisperse solid of frequency distribution $q_3(x)$, the corresponding use of Equation (86) leads to Equation (87):[13]

$$Q_3(x) = 1 - \frac{\int_{\ln T(\infty)}^{\ln T(t)} \frac{x}{K(x)}\, d\ln T}{\int_{\ln T(0)}^{\ln T(\infty)} \frac{x}{K(x)}\, d\ln T} \tag{87}$$

where $T = I/I_\infty$ ($I_\infty = I_A$) at time $t = \infty$ (solid-free). The difficulty in applying this relationship to sedimentation analysis has mainly to do with the extinction function $K(x)$; it depends on a total of four quantities:

- particle size x
- wavelength λ of the light used
- the optical constants of solid and liquid
- the aperture angle Θ of the optical system used.

There are three possibilities with respect to the extinction function:

- calculation from material data
- assumption of constancy
- experimental determination.

Calculation can in principle be done on the basis of the theory of Mie[125] (see also van de Hulst,[126] and Kerker[127]). Its use requires knowledge of the optical properties (ratio of refractive indexes) of solid and liquid, their absorption capacity (imaginary refraction index) and, furthermore, the well-founded assumption that the solid particles can be characterized by a spherical shape. Tables of refraction indexes and approximations of the extinction function are given in the literature (see Alex et al.,[1–12] Bernhardt[13]).

Theoretically, the extinction function must have the trend described in the following (see Figure 19). In the case of small aperture angles the function starts close to one for large particles ($\alpha = \pi x/\lambda > 100$). With decreasing particle size, its value grows to a maximum under strong oscillations and then rapidly decreases and turns into the curve of the Raleigh theory in the range $\alpha < 1$.

Practical cases often are far from these ideal conditions. Frequently, there is neither a spherical shape nor a homogeneous solid whose optical properties are known. Examples include most rocks, ores, coal, silicatic raw materials, and so on.

Figure 19 Extinction function dependent on Mie parameter $\alpha = \pi x/\lambda$ for different aperture angles θ; $m = 1.2$ (according to Weichert[128]). (Reproduced from Bernhardt,[13] Copyright 1994, with kind permission from Kluwer Academic Publishers.)

The influence of the aperture angle θ on the extinction function has been studied by Weichert.[128] Some of his results are represented in Figure 19.

It is evident that:

- The aperture angle θ controls the position of the final value to which the extinction function tends for large particles;
- for a large aperture angle θ, the assumption of a constant value of the extinction function for a wide range of fineness is more justified than for small θ.

The latter fact led Allen[129] to improve the wide angle photosedimentometer according to Harner and Musgrave[130] and Telle.[131] For $K(x) =$ constant, Equation (88) is obtained from Equation (87)

$$Q_3(x) = \frac{\int_{\ln T(t)}^{\ln T(\infty)} x\, d\ln T}{\int_{\ln T(0)}^{\ln T(\infty)} x\, d\ln T} \tag{88}$$

If the direct determination of the volume distribution $Q_3(x)$ is replaced by the surface distribution $Q_2(x)$, the very simple and well known relationship, Equation (89), is obtained:

$$Q_2(x) = \frac{\int_{\ln T(t)}^{\ln T(\infty)} d\ln T}{\int_{\ln T(0)}^{\ln T(\infty)} d\ln T} = \frac{\ln(I_\infty/I_t)}{\ln(I_\infty/I_0)} \tag{89}$$

where I_0 is I_A at time $t = 0$; I_∞ is I_A at time $t = \infty$ (solid-free); I_t is I_A at time t.

When using this approach it must be taken into account that while it is possible to measure up to the given range, strictly speaking there must not be any solid fractions below the smallest size indicated; the greater the actual fines fraction, the higher the error of measurement.

The problems mentioned describe the whole approach as unsatisfactory. Therefore, there have been attempts to determine experimentally the extinction functions for given materials and devices since the introduction of this sedimentation method.[129,130,132,133] While these essentially relate to measurements of narrowly classified or monodisperse materials, Johne and Ramanujam[134] describe a method based on the studies of Locher[135] for which the frequency distribution $q_3(x)$ of a calibration material has to be known.

Weichert[128] solved the problem by measuring the transmission of a sedimenting system dependent not only on the time t (or size x) but also the wavelength λ. He was able to show that even simultaneous measurement at three different wavelengths would be sufficient if the dependence of the refractive index on the wavelength could be neglected for the selected conditions. This method has the advantage that the simple procedure of modifying the photometric sedimentation analysis simultaneously provides the information required for the calculation of the size distribution, with the material and device dependent influences being taken into account.

Photosedimentometer. Photosedimentometers are subdivided into wide angle and small angle systems. Figure 20 gives a comparison of the two principles.

In the small angle photometer (aperture angle $\Theta \leq 3^\circ$), the light emitted by a lamp (1) is formed into a parallel bundle by a lens system (2); a part is transmitted to the suspension in a measurement cuvet (4) through a diaphragm (3). By means of diaphragm (5), the arriving radiation is transmitted to the detector (6) under a small aperture angle.

Figure 20 Photometer principles, (a) small angle photometer, (b) wide angle photometer. (Reproduced from Bernhardt,[13] Copyright 1994, with kind permission from Kluwer Academic Publishers.)

In contrast, no parallel light is used in the wide angle configuration; lamp (1), lens system (2) and diaphragm (3) are designed so that the suspension is transilluminated by a light bundle of the type shown. Since there is no diaphragm between cuvet (4) and detector (5), the aperture angle is very wide ($\Theta > 40^\circ$).

The two systems have occasionally been the subject of comparative analysis;[129,134] neither was revealed to be superior with respect to the other. This is why both systems are still in use.

Turbidity measurements for the characterization of colloid–chemical processes and conditions have been known for a long time (e.g. see von Hahn[105]). First studies on the use of this principle in sedimentation analysis for the determination of particle size distributions were done by Skinner and Boas-Traube[136] and later by Rose;[132] the latter developed a small-angle device which became known by the name of the manufacturer, Evans Electroselenium Ltd., London (EEL sedimentometer).

The simultaneous development of the wide angle technique can be traced back to investigations by Harner and Musgrave[130] and Telle,[131] the device described by the latter was built by Leitz, Wetzlar. Allen used the wide angle principle, initially without height adjustment.[129] Later he reported a new development that allowed the sedimentation vessel to be lower[16] and then one that allowed the optical system to shift upwards. The latter is known under the name of Ladal wide angle scanning photosedimentometer (WASP). A similar version, however, with downward shifting of the sedimentation vessel is distributed by Microsal, London, under the name Computerised WASP.

The Fritsch company, Idar-Oberstein, manufactures a wide angle device under the designation Scanning Fotosedimentograf (Analysette 20) in which the sedimentation vessel is fixed and the optical system is moved upwards at a constant velocity.

The small angle device Sedigraph 5500 L of Micromeritics, Norcross provides for the lowering of the measurement cuvet, albeit not at a constant velocity but following a scanning program in which the velocity diminishes with increasing sedimentation time. As a result of measurement, a surface distribution according to Equation (89) is recorded.

The spectral photosedimentometer described by Weichert[128] uses light of three different wavelengths. Both the sedimentation vessel and the small angle

optical system are at rest during measurement; however, the latter is a multiple system distributed along the sedimentation path.

A multiple optical system distributed along the sedimentation path is also used in the device called Lumosed which was developed by Staudinger et al.[137] A commercially available device from Retsch uses white light at three different sedimentation heights; a special procedure was developed for the combination of the results, which are evaluated under the assumption of a constant extinction function. At the same time, a number of values of the extinction function can be calculated by means of a calibration measurement with a substance of known distribution; these values can then be used in all measurements of the same material system.

In conclusion, another group of devices shall be mentioned which can be used in both gravitational and centrifugal fields. These are products of several important Japanese firms (Shimadzu Corp., Tokyo, Horiba, Kyoto, Seishin Enterprise Ltd., Tokyo); their main use, however, is as centrifuges. Therefore, they will be dealt with in section 4.3.

4.2.1.5 Methods Based on Gamma Attenuation

Fundamentals. Gamma radiation or X-rays of intensity I_E impinge on a suspension of thickness L, the intensity I_A after transillumination is calculated on the basis of the Lambert–Beer law, Equation (90):

$$\ln \frac{I_E}{I_A} = \mu_{m,eff} \rho_{eff} L \tag{90}$$

For a homogeneous solid in a liquid the very simple Equation (91) holds:

$$Q_3(x) = \frac{c_V(t)}{c_0} = \frac{\ln(I_\infty / I_t)}{\ln(I_\infty / I_0)} \tag{91}$$

For two solids (with different particle size distributions, different densities and mass attenuation coefficients) the measured distribution is produced by a more complicated relationship which was developed by Bernhardt.[116] He found that the differences between the measured and the true particle size distributions are only considerable for large mass portions near the maximum of the frequency distribution. The theory was confirmed experimentally for the measurement of mixtures of SiO_2 and Fe_2O_3 by using a sedigraph 5000 D (see Figure 21).

In general, it can be said that the particle size distribution of the components essentially determines the shape of the error curve and the solid mass proportions essentially control the value of the errors. It is difficult to give a general assessment of the effects of the other parameters, density, attenuation coefficient and solids concentration.

Gamma-ray and X-ray Sedimentometer. The first to propose the use of X-rays for incremental sedimentation analysis were Brown et al.[138] Their commercial system (ICI Stevenston, Scotland) is described in Allen.[16] Later improvements used different X-ray sources[139–142] and radionuclides.[143,144] Rumpf et al.[68] deal with the criteria of selection for different types and energies of sources as well as the required activity. Among more recent developments, two deserve to be mentioned: the LADAL X-ray sedimentometer[16,144] has a fixed

Figure 21 Total systematic error due to the density and attenuation coefficient of heterogeneous solids ($SiO_2 + Fe_2O_3$) (p_1 mass proportion of SiO_2): (a) calculated; (b) experimental (Sedigraph 5000 D). (Reproduced from Bernhardt,[13] Copyright 1994, with kind permission from Kluwer Academic Publishers.)

Figure 22 Schematic diagram of Sedigraph 5100.

measurement cell. After a certain time, which can be selected within defined limits, the radiation source and the proportional counter are moved upwards in the direction of the liquid surface at a constant velocity (approx. 1.5 cm min^{-1}). Maximum sedimentation height is 18 cm, the minimum value is 1 cm. The recommended range determined by these geometrical conditions is between 2 and 100 µm. The necessary solids concentration is $c_V \leq 1\%$ for materials with an atomic number ≥ 12.

Sedigraph 5000 D, 5000 ET or 5100[140,145] have a measurement cell moving downwards at a reducing velocity between the radiator (air-cooled X-ray tube with tungsten spot) and the scintillation counter. A scheme for the computer controlled Sedigraph 5100 is given in Figure 22.

A well-dispersed suspension is introduced into a sample chamber from which it circulates through the analysis cell by means of a peristaltic pump. At the start point of the analysis the pump stops and the particles begin to settle in the analysis cell. The measurement of the X-ray attenuation begins near the cell bottom, and because of the shift down the cell the distances between the particles become smaller and smaller. In this way acceptable analysis times are obtained even for very small particle sizes under 1 µm. After the analysis the suspension is pumped to a waste reservoir and using a second peristaltic pump, fresh rinse liquid flows through the system.

The Sedigraph device family has established itself well since its invention.[146–150]

4.2.1.6 Repeated Decanting The method of repeated decanting goes back to the elutriation analyses that were usual in soil analysis until some time ago (see older standard works[103,105,151]). This technique is related to names such as Appiani, Atterberg, Kühn, Wagner, Wahnschaffe, and so on; the principle is shown in Figure 23.

Figure 23 Principle of repeated decanting.

Even though this method is probably not used nowadays for sedimentation analysis, it is a simple method for preparative production of particle fractions below the sieving limit. This is why it will be briefly considered here.

If the suspension which was homogeneous at time $t = 0$ is allowed to sediment in a vessel (see Figure 23), the particle mass m_a in the bottom space after time t is given by Equation (92)

$$\frac{m_a}{M} = 1 - \frac{h_1}{h_2} \int_0^{x_t} 1 - \left(\frac{x}{x_t}\right)^2 q_3(x)\,dx \qquad (92)$$

Now in decanting, the volume of the suspension above the bottom space is removed after a given time t and then replaced by solid-free liquid up to level h_2. After mixing, the supernatant suspension is again removed after time t and so forth, until the amount of solids $m_s/M = 1 - m_a/M$ tends to zero and $m_a/M = 1 - Q_3(x)$ can be assumed with sufficient accuracy. This, of course, is why repeated decanting can be looked upon as an incremental method.

Rumpf and Alex[152] analyzed the process of decanting by calculating the grade efficiency curve after n times. Decanting has to be repeated very often to obtain a high cut sharpness, that is, it requires much time. For

instance, at least 32 decanting steps are required for a proportion <0.1% for $x = 0.9\,x_t$, but even then approx. 5% of the particles with $0.95\,x_t$ that were in the feed are still present in the bottom space. An interesting result is that a drastic reduction in the bottom space (h_1/h_2 near 1) does not give any improvement. Suggestions for the suitable design of decanting vessels are given in the literature.[16,103,105,151–153]

4.2.2 Cumulative Suspension Methods

4.2.2.1 Fundamentals There are two types of cumulative suspension methods:

- methods based on the measurement of m_a (the amount of solids that have sedimented from the suspension volume)
- methods based on the measurement of m_s (the amount of solids still in the suspension volume).

Consequently, there are two different basic relationships for the determination of the particle size distribution, Equations (93) and (94)

$$1 - Q_3(x_t) = \frac{1}{M}\left(m_a - t\frac{\mathrm{d}m_a}{\mathrm{d}t}\right. \quad = \frac{1}{M}\left(m_a - \frac{\mathrm{d}m_a}{\mathrm{d}\ln t}\right. \tag{93}$$

$$Q_3(x_t) = \frac{1}{M}\left(m_s - t\frac{\mathrm{d}m_s}{\mathrm{d}t}\right. \tag{94}$$

where M is the total solid mass in the suspension.

Equations (93) and (94) provide the basis of all cumulative principles. Their derivation originated with Odén[106] but is also found in later works, sometimes in a modified form.[103,154,155]

4.2.2.2 Measurement of Sedimented Amount in Solids All known versions of sediment measurement differing only in the physical measuring principle are shown in Figure 24.

Figure 24 Cumulative suspension methods; measurement of sedimented solid mass m_a. (a) Sedimentation balance, (b) sedimentation column, (c) β-backscattering. (Reproduced from Bernhardt,[13] Copyright 1994, with kind permission from Kluwer Academic Publishers.)

Sedimentation Balance. The principle of the sedimentation balance (Figure 24a) was technically realized by Odén as early as 1915/1916[106] and in 1920 was available as an automatic device which registered the sedimented mass m_a dependent on time (see Geßner[103]). Since then, there have been many successors that have maintained the basic principle, only adapting the device to the state of the art.[130,154,156–162]

The way the balance pan is arranged has an influence on the measurement range. An arrangement like that schematically represented in Figure 24(a) leads to density convection flows at the pan brim[1–12,69] so that parts of the solids < 3–4 µm are transported under the pan and are thus lost for the measurement. The effect is avoided by a design according to Alex et al.[1–12] and Bürkholz.[163]

In view of their automatic mode of operation and their low solids concentration (<0.1 vol%), sedimentation balances were widely used in the past. This is demonstrated by the multitude of commercial designs (e.g. Gallenkamp (England), Cahn (USA), Mettler (Switzerland), Sartorius (Germany), Shimadzu (Japan)).[164] Because of their relatively long analysis time, nowadays these balances are used only where the advantages outweigh this disadvantage or where other systems cannot be used (e.g. Kowalski[165]).

For the older designs, the measured curve $m_a(t)$ was evaluated graphically according to Equation (93) followed by further improvements (see in von Hahn[105]).

Sedimentation Column. Particularly among English publications, there is information concerning the use of so-called sedimentation columns whose basic principle is traced back to Stairmand;[166] similar designs were already mentioned by Geßner[103] and von Hahn.[105] The principle is represented in Figure 24(b). The solid mass sedimented from a very thin suspension ($c_V < 0.1\%$) is released from the vessel at staggered time intervals, and the sample volume (10 cm^3) is automatically replaced by solid-free liquid from a second vessel. There are even more simple solutions (see Allen[16]) which do not include a liquid reservoir. Evaluation is done either by using Equation (93) or an approximation method proposed by Stairmand.[166]

Beta Backscattering. The principle represented in Figure 24(c) is based upon beta radiation being directed towards the solids sedimented on the bottom of the suspension vessel and the subsequent measurement of the backscattered radiation intensity. According to Hardwick and Laundy[167] the backscattered intensity depends only

on the so-called effective atomic number z_{eff} of the investigated material.

As an example: for water, z_{eff} is approximately 7, for ZrO_2 it is approximately 32. This difference produces the measurement effect. By the solid sedimenting to the bottom, water is displaced so that z_{eff} and thus the backscattered intensity change with the solid mass within a certain range of layer thickness.

An alternative device using β-radiation is the transmission scheme developed by Curzio.[168] Here, the radiation source is fastened above the bottom in such a way that the radiation is attenuated by the solid on the bottom dependent on the layer thickness before it reaches the detector.

4.2.2.3 Measurement of Amount of Solids in Suspension
The principles based on this method are represented in Figure 25.

The manometer method (Figure 25a) goes back to works by Wiegner,[107] Geßner[103] and von Hahn.[105] Lange and Gast[169] used a highly sensitive pressure measurement device which allowed a drastic reduction of the sedimentation height. This method was later been automated.[170] The particle size distribution is calculated from the measured pressure curve $\Delta p(t)$ by Equation (95)

$$Q_3(x) = \frac{\Delta p(t)}{\Delta p_0} - \frac{t}{\Delta p_0}\frac{\mathrm{d}\Delta p}{\mathrm{d}t} \tag{95}$$

In the case of cumulative diving methods, a distinction has to be made between those with constant and those with variable immersion depth (see Figure 25b and c). The use of these methods is simplest if the areometers have a constant cross-section over their entire length; other shapes, however, are possible as well.[103,105,153,171]

Figure 25 Cumulative suspension methods; measurement of solid mass in suspension. (a) Manometer method, (b) diving balance, (c) swimming balance, (d) single decanting. (Reproduced from Bernhardt,[13] Copyright 1994, with kind permission from Kluwer Academic Publishers.)

The diving balance (Figure 25b) allows the weight force $P(t)$ of the diving body to be determined dependent on the time t and the particle size distribution to be calculated from Equation (96)

$$Q_3(x) = \Pi - t\frac{\mathrm{d}\Pi}{\mathrm{d}t} \tag{96}$$

where

$$\Pi = \frac{P(t) - P_\infty}{P_0 - P_\infty} \tag{97}$$

where $P_0 = P$ for $t = 0$, $P_\infty = P$ for solid-free liquid.

The swimming balance (Figure 25c) indicates the variable immersion depth $h(t)$; if h_0 (at $t = 0$) and h_∞ (solid-free liquid) are known as well, the particle size distribution is calculated according to Equation (98):[153,171]

$$Q_3(x) = \frac{h_0}{h(t) - h_0}\frac{h_\infty - h(t) + t(\mathrm{d}h/\mathrm{d}t)}{h(t) - t(\mathrm{d}h/\mathrm{d}t)} \tag{98}$$

Single decanting (Figure 25d) as a cumulative method was investigated by Bennert[172] and Schultz;[173] the experimental side of decanting is described in the literature.[16,103,105,151–153,172] Measuring the mass m_S above the bottom space in several vessels at different times t or even in one vessel with different h_1 and t valves, the particle size distribution is determined by the modified Equation (94), Equation (99)

$$Q_3(x) = \frac{h_2}{h_1}\frac{1}{M}\left(m_s - t\frac{\mathrm{d}m_s}{\mathrm{d}t}\right. \tag{99}$$

4.2.3 Line Start Methods

If a thin suspension layer of thickness $\Delta h \ll h$ is arranged on top of a solid-free liquid column and disturbance-free sedimentation is secured, we will immediately obtain in depth h:

- for incremental measurement: the frequency distribution $q_3(x)$,
- for cumulative measurement: the distribution $Q_3(x)$.

The fact that this is a very attractive possibility was the reason that the range of application of this method was constantly investigated or attempts were made to expand it by the development of new devices; this, however, proved possible only to a certain limit. The main reason for this is the difficulty of ensuring disturbance-free sedimentation. Mainly at the beginning, instability occurs caused by the difference in density between the suspension and the solid-free liquid. The

consequence is streak-type vortexing leading to solid particles entering the liquid with high speed. The only reliable method of solving this problem is the density gradient method known from centrifugal equipment (see Allen et al.[1–12]). In gravity sedimentation, however, elimination of this effect has been tried by reduction of the solids concentration[174] or extreme expansion of the sedimentation path.[146]

The quantity measurement is exclusively cumulative and usually restricted to manometric measurement or gravimetric measurement in the form of a sedimentation balance.[146,174] A further device, the so-called US sedimentometer[149] uses the sediment volume as a measured variable; its preferential use in the manufacture of abrasives, however, obviously is due to the fact that the line start method offers a good possibility of determining even very tiny fractions of large grains, which is decisive in this area.

A device proposed by Muschelknautz[175] deserves to be mentioned; it imitates cumulative layer formation by weighing in two sedimentation vessels of different height. This removes all the above problems.

The use of air as a sedimentation medium offers the possibility of shifting the lower application limit to a few micrometers while maintaining long sedimentation paths.[176] This method was used by several authors.[177–179] The Micromerograph[177] uses a sensitive torsion balance for quantity measurement. The solid is fed by pressurized air; the accompanying dispersion effect is assumed to be sufficient for most cases.[180,181] A device described by Kouzov[178] uses a conventional air gun; at the same time, this is one of the rare cases of an incremental quantity measurement (photometric evaluation of plates exposed for different periods of time which are installed at the bottom of the sedimentation vessel). Another application of the line start method is the determination of the drop size of sprays using a sedimentation balance.[179]

4.3 Methods Used in the Centrifugal Field

4.3.1 Fundamentals

4.3.1.1 Modified Stokes Law In order to overcome the disadvantages of gravity sedimentation in the range of small particles $< 1\,\mu m$ (e.g. diffusion, long measurement periods), a centrifugal field can be used instead. However, the acceleration b is a function of radius r ($b = w^2 r$) so that Stokes velocity becomes, Equation (100)

$$\frac{dr}{dt} = \frac{\Delta\rho}{18\eta} w^2 r x^2 \tag{100}$$

For constant angular velocity w, an integration for any sedimentation between an inner radius r_i and an outer radius r_a yields, Equation (101)

$$\ln \frac{r_a}{r_i} = \frac{\Delta\rho}{18\eta} w^2 x^2 t \tag{101}$$

In practice, acceleration and deceleration phases will always occur in addition to phases of constant angular velocity; therefore, the curve of $w(t)$ has to be taken into account in the integration, Equation (102):

$$\ln \frac{r_a}{r_i} = \frac{\Delta\rho}{18\eta} x^2 \int_0^{t_{max}} w^2(t)\, dt \tag{102}$$

To be able to calculate the particle size x for a given running time t_{max} on this basis, $w^2(t)$ can be plotted against t, and the area under the curve can be determined. Rumpf et al.[68] propose the use of an effective time t_{eff} for the case of a constant acceleration and deceleration, Equation (103):

$$t_{eff} = \frac{t_1}{3} + (t_2 - t_1) + \frac{t_3 - t_2}{3} \tag{103}$$

where t_1 is the end of acceleration phase, t_2 is the start of deceleration phase, and t_3 is the end of deceleration phase.

The incremental and cumulative principles used for quantity measurement in centrifuges are nearly the same as in the gravitational field. In the following, the theoretical basis will be briefly described (see also several overviews[13,16,53,182–184]).

4.3.1.2 Quantity Measurement for Suspension Methods; Incremental Principle The suspension level in the centrifuge vessel reaches radius r_i. There is an incremental measurement device at r for determining the solids volume concentration $c(r, t)$. The bottom of the suspension vessel is at radius r_a. Then the integral Equation (104) holds

$$\frac{c(r,t)}{c_0} = \int_0^{x_t} \exp\left\{-2\frac{\Delta\rho}{18\eta} w^2 x^2 t\right\}^2 q_3(x)\, dx \tag{104}$$

and for a constant angle velocity, Equation (105)

$$\frac{c(r,t)}{c_0} = \int_0^{x_t} \exp\left\{\left(\frac{x}{x_t}\right)^2 \ln \frac{r_i}{r}\right\}^2 q_3(x)\, dx \tag{105}$$

Equations (104) and (105) are fundamental equations for incremental suspension methods in the centrifugal field. Their use in the evaluation of measured values depends on the experimental approach. The following procedures are possible:

1. The dependence of the solids concentration on time t is determined at distance r. In this case, there is no general solution to Equation (104) for the particle

size distribution that is being sought, so there are various approximations. The simplest and most common was proposed by Norton and Speil[185] assuming that r/r_1 tends to 1, which is true only for centrifuges with big rotors and short sedimentation paths (long-arm approximation). Evaluation is done as in the gravity field but taking into account the increased acceleration. The error of this approximation in comparison with an exact evaluation was investigated by Alex.[186]

There is also the theory developed by Kamack[187] which reaches an approximate solution by assuming that the dependence of the solids concentration is linear between two measurement points t_1 and t_2. Then, Equation (106) can be written:

$$\frac{c(x_t, k')}{c_0} = \sum_{l=1}^{k} q_3(x_{t,l}) B_{k,l}$$

$$B_{k,l} = \int_{x_{t,l-1}}^{x_{t,l}} \exp\left\{ \left(\frac{x}{x_{t,k}}\right)^2 \ln \left(\frac{r_i}{r}\right)^2 \right\} \mathrm{d}x \quad (106)$$

obtaining a linear set of equations for the discrete values of $q_3(x_{t,l})$.

2. The solids concentration is measured dependent on the radius r at a fixed time t. Equation (105) then can be differentiated with respect to x_t, and we obtain Equation (107):[53,68]

$$Q_3(x_t) = \int_0^{c(r)/c_0} \left(\frac{r}{r_i}\right)^2 \mathrm{d}\,\frac{c(r)}{c_0} \quad (107)$$

Hence, if $c(r)/c_0$ is plotted against $(r/r_i)^2$, the distribution is determined by integration.

3. Svarovsky and Svarovska[188] use a solution of Equation (104) which was also proposed by Kamack, obtained for the distribution after time t (when the particle size x_t passes the measurement level). Their equation is an exact solution but the contained convolution integral can be solved only numerically. Therefore, Svarovsky and Svarovska[188] replaced it by an analytical approximation easily produced by an analogous calculation scheme, enabling the continuous evaluation of the sedimentation curve. A further solution was suggested by Fautz.[184]
4. Finally, the fundamental equations can also be solved by using analytical distribution functions for $q_3(x)$ and determining their parameters.[188]

4.3.1.3 Quantity Measurement for Suspension Methods; Cumulative Principle The mass m_a/M which is in the bottom space $r_{a2} - r_{a1}$ after time t is given by Equation (108)

$$\frac{m_a}{M} = 1 - \int_0^{x_t} \frac{r_{a1}^2 \exp\left\{(x/x_t)^2 \ln (r_i/r_{a1})^2\right\} - r_i^2}{r_{a2}^2 - r_i^2} q_3(x)\,\mathrm{d}x \quad (108)$$

If the cumulative measurement is organized so that the mass that sedimented at the bottom is determined (sedimentation balance), that is $r_{a1} = r_{a2} = r_a$, Equation (108) is simplified to Equation (109)

$$\frac{m_a}{M} = 1 - Q_3(x_t) + \int_0^{x_t} \frac{1}{1 - (r_i/r_a)^2} \times \left[1 - \exp\left\{\left(\frac{x}{x_t}\right)^2 \ln \left(\frac{r_i}{r_a}\right)^2\right\}\right] q_3(x)\,\mathrm{d}x \quad (109)$$

This is the relationship which was indicated by Romwalter and Vendl.[189] For the case where m_a/M is measured dependent on time there is a well-known solution originally proposed by Robinson and Martin[190] [cited by Sullivan and Jacobsen[183]]. An approximation method was suggested by Lloyd et al.[191]

As with the incremental methods, there are exact solutions for the case where measurement is dependent on the radius at a constant time. The first possibility is to measure the sedimented mass m_a/M dependent on the inner radius r_i. According to Brown[192] the solution is, Equation (110)

$$1 - Q_3(x_t) = \mu(r_i) - \frac{r_a^2 - r_i^2}{2r_i} \frac{\mathrm{d}\mu}{\mathrm{d}r_i} \quad (110)$$

where $\mu = m_a/M$.

A second possibility is to vary the outer radius r_a according to a proposal made by Donoghue and Bostock[193] so that, Equation (111)

$$1 - Q_3(x_t) = \mu(r_a) + r_a \frac{r_a^2 - r_i^2}{2r_i^2} \frac{\mathrm{d}\mu}{\mathrm{d}r_i} \quad (111)$$

If the solid mass in suspension m_S is responsible for the measured effect, Equation (112) holds:

$$\frac{m_S}{M} = \int_0^{x_t} \frac{1}{1 - (r_i/r_a)^2} \exp\left\{\left(\frac{x}{x_t}\right)^2 \ln \left(\frac{r_i}{r_a}\right)^2\right\} q_3(x)\,\mathrm{d}x \quad (112)$$

For repeated decanting until the solid mass m_S/M in the supernatant liquid tends to zero (this is absolutely usual for preparation purposes) $m_a/M = 1 - Q_3(x_t)$ for the solid mass in the bottom space. Rumpf and Alex.[152] have again developed the grade efficiency function dependent on the number of decanting steps to approximate this state; see examples in Bernhardt.[13]

In single decanting, the solid mass m_S/M in the volume above the bottom space is usually determined. To obtain the distribution $Q_3(x_t)$, Weichert[194] has proposed a

similar method to that of incremental analysis: single decanting operations are carried out at different times and m_S/M is determined dependent on time t. Linearity is assumed between the measurement points so that we can write Equations (113) and (114):

$$\frac{m_S(x_{t,k})}{M} = \sum_{l=1}^{k} q_3(x_{t,l}) A_{k,l} \tag{113}$$

$$A_{k,l} = \int_0^{x_t} \frac{\exp\left\{(x/x_t)^2 \ln (r_i/r_{a1})^2\right\} - r_i^2/r_{a1}^2}{1 - r_i^2/r_{a2}^2} q_3(x)\,\mathrm{d}x \tag{114}$$

For $q_3(x_{t,l})$, a linear set of equations is again obtained by analogy with Kamack's theory.[187]

4.3.1.4 Quantity Measurement for Line Start Methods The mathematical difficulties of the suspension methods have repeatedly led to the use of line start methods in sedimentation centrifuges. As in the gravity method, a thin suspension layer has to be brought to the top of a solid-free liquid. Then, the frequency distribution $q_3(x)$ (incremental measurement) or the distribution $Q_3(x)$ or $1 - Q_3(x)$ (cumulative measurement) is obtained directly (with restrictions for light optical incremental methods[16]). The disadvantage of this simplification, however, is the considerable experimental difficulties caused by the formation of streak-type mixing phenomena at the interface between suspension and pure liquid which falsify the result. A detailed description and wide bibliography are given by several authors.[1–12,68,195,196] Accordingly, the cause of this problem is mainly the instability of the superposed layers which leads to a special form of density convection flow. According to Alex et al.,[1–12] two conditions have to be met to prevent such streak formation:

- The density of the superpositioned suspension has to be smaller than that of the pure sedimentation liquid. Both liquids have to be miscible to avoid additional problems caused by wetting.
- The solids concentration has to be small enough that the particles travelling from the suspension positioned on top of the pure sedimentation liquid cannot produce density convection flows by their presence. This is guaranteed for solids concentrations under 0.01%, a range for which, however, none of the usual methods of quantity measurement works.

Therefore, the so-called density gradient method has to be used as the only existing way of avoiding streak formation; its successful application is described by Alex et al.,[1–12] Brugger[197] and Coll and Searles.[198] Its content is to introduce into the centrifuge, in a suitable way, a sedimentation liquid whose density increases in the radial direction. This requires some experimental effort which will probably not be spent on routine analyses, since the problems of suspension methods can be solved by modern computer equipment.

In contrast, Kaye[199] holds the opinion that the above difficulties in the line start methods in many cases are caused by the lack of stability of the centrifuge structures at high rotational speed.

4.3.2 Sedimentation Centrifuges

Since the first work by Svedberg and co-workers[52,108] on the use of centrifuges for particle size analysis, there have been a large number of publications on methodological and technological solutions. An overview and historical development are given in the monographs by Allen,[16] Chodakov and Judkin,[182] Batel,[153] Bernhardt,[13] Köster,[151] Geßner[103] and von Hahn[105] as well as by the Analytical Methods Committee.[14]

On the whole, the experience seems to have been accepted according to how much methodological and technological effort is needed for accurate measurement. This applies both to the case of sedimentation in orbiting vessels (bucket centrifuges) and to the rotation of the suspension in a cylindrical vessel like a concentric ring (disk centrifuges).

4.3.2.1 Centrifuges with Incremental Measurement The three main principles are shown in Figure 26.

Figure 26 Basic principles of sedimentation centrifuges with incremental quantity measurement; (a) pipette centrifuge, (b) photosedimentation centrifuge, (c) X-ray or γ-ray centrifuge. (Reproduced from Bernhardt,[13] Copyright 1994, with kind permission from Kluwer Academic Publishers.)

Pipette Centrifuge. This device (Figure 26a) is usually a disk centrifuge. The suspension rotates like a ring in the disk rotor (1) into which between four and eight pipettes stand and participate in the rotation. It has to be ensured that a tight connection is created between the rotating pipette shaft and the part of the sample which is at rest (stopcock (4), glass vessel (5)), for instance by device (3). When a vacuum is applied, the suspension sample flows into the sample vessel (5) from where it can be taken for further treatment (drying, weighing). The evaluation is done either in the gravity field (long-arm approximation), as for example in the centrifuges by Slater and Cohen[200] or Gupta,[201] or by one of the approximations of Equation (105) as for example in the centrifuge according to Kamack[187] or the modern Ladal pipette centrifuge[202] and the Andreasen pipette centrifuge of Fritsch.

Photosedimentation Centrifuge. In the older types of centrifuge that use this principle, the centrifuge rotor (1) is a disk (see Figure 26b). Through the ring-shaped suspension, a light beam which is produced by the lamp (2) and optical device (3) (lens, prism) is emitted at a certain point and falls on the detector (4) on the opposite side. Light source and detector can also be shifted in the direction of the axis to shorten the measurement time (e.g. Allen and Khalili[203]).

The first photosedimentation centrifuge was developed by Kaye and Jackson;[204] it was followed by the version which became known as the Joyce–Loebl centrifuge.[1–13] In both cases, a line start technique was used, with the usual problems in spite of special prescriptions (buffer layers etc.).[195,196] Allen tried to circumvent the problems by developing a centrifuge with suspension technique (Ladal photo centrifuge[203]) which involved the evaluation problems discussed by Lloyd et al.[191] and Svarovsky and Svarovska.[188]

Several modern Japanese sedimentation centrifuges have abandoned the disk rotor and use rotating measurement cells with a rectangular cross-section instead. Two of these cells are mounted on the rotor, one being filled with suspension and the other opposite being used for balancing or reference purposes. When the rotor is at rest, the devices can be employed as gravity photosedimentometers.

As discussed already, incremental photoelectric quantity measurement requires knowledge of the extinction function, and particularly so in the measurement range of the centrifuges (0.01–10 μm). In the centrifuge devices of Shimadzu and Horiba, a solution to this problem has been attempted by the possible use of a fixed standard extinction function or an extinction function obtained in a different way. This approach is not satisfactory either, since the effective extinction function of the investigated material is not known in many cases and the user does not know how great is its deviation from standard.

Weichert[128] solved this problem by an experimental determination of the extinction function, however, the expense of the measurement and calculation is very high. This can be the reason for the fact that there has been no commercial use of the method.

X-ray or γ-ray Centrifuges. As is well known, the problem of the extinction coefficient does not exist for X-rays or γ-radiation. The principle represented in Figure 26(c) is completely analogous to the light optical method. The disk-shaped rotor (1) is subject to radiation from a suitable radiation source (2) at a certain point in the suspension ring; the intensity of the radiation incident on the opposite side is measured by the detector (3). Source (2) and detector (3) can be shifted in a radial direction to reduce the measurement time. The Ladal γ-ray centrifuge[202,205] uses a radioactive isotope (Pm 147/Al) and a scintillation counter. To obtain a measurable attenuation effect, the solids concentration has to be considerably higher than with photoelectric methods. This may lead to restrictions on use since the stability of the suspension strongly depends on the solids concentration for very small particles.

The development of a disk centrifuge (Du Pont/Brockhaven Scanning X-ray Disc Centrifuge) is described by Allen.[206] This device can be used both in the gravity field and the centrifugal field, that is, in a measurement range between 0.01 and 100 μm. Finely focussed X-rays are directed to the sedimentation path by a scanning program so that only a few minutes are required for the whole measurement.

4.3.2.2 Centrifuges with Cumulative Measurement

Some of the best known principles of cumulative sedimentation centrifuges are represented in Figure 27.

Manometer Centrifuge. In this scheme borrowed from gravity sedimentation (Figure 27a), on the centrifuge rotor (1) there is only one measurement cell (2) at which the pressure difference between upper and lower end is measured. The counterweight (4) ensures an equilibrium. By means of cables (3), the pressure is supplied from the rotating centrifuge shaft to the data transmitter (5) and then to the differential pressure converter (6) producing an electrical signal for further evaluation. The development of the device originated with Böwing and Gast;[207] Lauer[208] reported on further developments and the version marketed by Alpine. This centrifuge is designed so that the long-arm approximation and the related evaluation algorithm can be employed. The principle has been improved by Jimbo et al.[209] who used a highly sensitive pressure measurement technique which

Figure 27 Basic principles of sedimentation centrifuges with cumulative quantity measurement. (a) Manometer centrifuge, (b) centrifugal sedimentation balance, (c) eccentric centrifuge. (Reproduced from Bernhardt,[13] Copyright 1994, with kind permission from Kluwer Academic Publishers.)

allowed the required solids concentration to be reduced further.

Centrifugal Sedimentation Balance. Solids sediment are placed on balance pans either in measurement cells of suitable design or in the disk rotor; the first principle is represented in Figure 27(b). On the rotor (1) there is a measurement cell (2) filled with suspension, in which there is a balance pan (3) and into which a diving body (4) is immersed. The cell (7) installed on the opposite side contains solid-free liquid. Thus, the measurement effect for the sedimenting mass is a change of pathlength measured by device (5) and supplied to the evaluation unit (6). Bürkholz et al.[210] and Muschelknautz[175] have reported on the development of such a balance. Similar devices with light optical scanning were introduced by Tarasov and Chodakov.[211]

Eccentric Centrifuge. An original solution for the cumulative measurement in a sedimentation centrifuge was found by Kaya and Yokoyama;[212] the principle is represented in Figure 27(c). In the rotor (1) two measurement cells are arranged opposite each other, one of which (2) contains the suspension (solids concentration approx. 3 wt%) and the second of which (3) contains solid-free liquid. Owing to the shift of the gravity center in cell (2) caused by the sedimentation process, an eccentricity variable in time is generated leading to a deflection of the rotor shaft. The relationships between sedimenting mass and eccentricity, on the one hand, and between eccentricity and deflection, on the other hand can be described by formula.[212] For evaluation, the rotational speed of the rotor shaft has to be known (tachometer (7)) in addition to the deflection measured by parts (4) and (5). The drive (6) propels the centrifuge; the evaluation unit (8) processes the information obtained (rotational speed and deflection) to determine the searched distribution function.

In conclusion, it should be noted for the sake of completeness that single and repeated decanting is also possible in centrifuges. A typical example is the Joyce–Loebl disc centrifuge.

LIST OF SYMBOLS

a	Half-axis; radius
A	Factor; area; feed material (index); buoyancy
A_P	Buoyancy of a particle
Ar	Archimedes number
A_V	Scattering section of individual particle related to particle volume
B	Constant; factor
$B_{k,l}$	Integral function
c	Half-axis; concentration
c_0	Concentration at time $t = 0$
c_{eff}	Effective solids concentration
c_m	Solid mass concentration
$c_{m,0}$	Solid mass concentration at time $t = 0$
c_V	Solid volume concentration
c_w	Drag coefficient
$c_{w,st}$	c_w according to Stokes
C_L	Factor
D	Function; diffusion coefficient
D_H	Thickness of hydrate sheath
f	Systematic error

f_x	Error in particle sizes
F_P	Projection area of a particle vertical to flow direction
g	Gravitational acceleration
G	Weight
G_P	Weight of a particle
h	Height; depth; distance from the particle surface
h_M	Height of measurement level
I	Radiation/light intensity
I_A	Intensity after transmission
I_E	Intensity prior to transmission
I_t	I_A at time t
I_∞	I_A at time $t = \infty$ (solid-free)
I_0	I_A at time $t = 0$
k	Boltzmann constant ($=1.38 \times 10^{-13}\,J\,K^{-1} = 1.38 \times 10^{-16}\,g\,cm^2\,s^{-2}\,K^{-1}$); exponent
K	Shape correction factor
$K(x)$	Extinction function; corrected cumulative distribution
l	Distance between the centers of two spheres
l_1	Distance of sphere center from a wall
L	Distance between two walls; transilluminated length; mean free path
Lj	Ljaščenko number
m	Parameter of Gates–Gaudin–Schumann distribution; refractive index; coefficient
$m(t)$	Solid mass at time t
m_0	Solid mass at time $t = 0$
m_a	Particle mass in bottom space of a sedimentation vessel
mea	Measured (index)
m_p	Particle mass
m_S	Particle mass above bottom space of a sedimentation vessel
M	Mass (total); moment
M_M	Molecular mass
$M_{k,r}$	k th moment related to zero, quantity r
n	number
n_F	Refractive index (fluid)
N	Number
N_L	Avogadro number ($N_L = 6.022 \times 10^{23}\,mol^{-1}$)
p	Fraction, shape factor $= c/a$, pressure
P	Weight; pressure
P_0	P at time $t = 0$
P_∞	P at time $t = \infty$ (solid-free)
q_3	Density distribution with quantity type volume, mass
Q	Cumulative distribution
Q_0	Q with quantity type number
Q_2	Q with quantity type surface
Q_3	Q cumulative distribution with quantity type volume, mass
r	Radius
r_a	Outer radius
r_i	Inner radius
R	Radius; factor
Re	Reynolds number
R_P; R_R	Functions for plates or rods
S_P, S_R	Functions for plates or rods
t	Time
t_{99}	Time for $v/U = 0.99$
t_{eff}	Effective time
T	Temperature; transmission
$T(x)$	Cut function, grade efficiency function
T_P, T_R	Functions for plates or rods
U	Terminal velocity of a particle
U_0	U in ideal case (without external influence)
U_a	U in a-direction
U_c	U in c-direction
U_P, U_R	U for plates or rods
U_{rel}	Relative velocity
U_{st}	U according to Stokes
U_x	U in x-direction
U_v	Stationary sedimentation velocity
U_z	U in z-direction
v	Velocity
V	Volume; energy of interaction; particle volume (index)
V_A	Attraction energy
V_{el}	Energy of electrostatic repulsion
V_P	Volume of particle
V_{ster}	Steric repulsion energy
W_{El}	Drag force to an ellipsoid
W_P	Drag force of a particle, a plate
W_{St}	Drag force according to Stokes
x	Particle size; coordinate axis
x_{50}	Median of distribution
x_a, x_c	Axis of a spheroid
x_A	Diameter of a sphere of equal surface area
x_F	Equivalent projected diameter
x_S	Apparent particle size
x_{st}	Particle size according to Stokes
x_t	Particle size which has passed through distance h after time t
x_V	Diameter of a sphere of equal volume
z	Coordinate axis; valency
z_{eff}	Effective atomic number
α	Mie parameter; angle in degrees or rad; degree of desagglomeration
β	Angle; coefficient; function; degree of agglomeration; quantity type (index)
Δh	Measurement gap height
Δp	Pressure difference
Δp_0	Pressure difference at time $t = 0$
$\Delta\rho$	Density difference $\rho_s - \rho_m$

ΔQ	Quantity proportion in a particle size class
ζ	Flow (zeta) potential
η	Viscosity of medium
Θ	Angle
κ	Dynamic shape factor
λ	Wavelength
μ_m	Mass attenuation coefficient
$\mu_{m,eff}$	Mass attenuation coefficient of a mixed material
Π	Relative pressure difference
ρ	Density
ρ_{eff}	Effective density of a mixed material
ρ_H	Density of hydrate sheath
ρ_m	Density of medium
$\rho_{m,0}$	Density of pure liquid
ρ_S	Density of solid
φ	Suspension density
φ_0	Suspension density at time $t = 0$
$\varphi(h, t)$	Suspension density at time t in depth h
ϕ_0	Gaussian normal distribution
ψ_W	Shape factor according to Wadell (sphericity)
ψ_{HC}	Shape factor according to Heiss and Coull (circularity)
w	Angular velocity

Diamant	W + sca, W + sp6, W + sp3, W + Aerosol OT, EL

Earth, soil	W + sp4, W + so, W + EG, BP + EL
Feldspar	W + sp6, W + sp3, W + sp4, W + so
Flour	PM + oa, BI, DP + BI, DP, AA, EL, CN, CL
Garnet	W + sp6
Glass	W + sp4, W + sp3, W + sk6, W + Dispersol T, W + Lissapol NX, W + Triton X-100, W + sp6, BL, CL, W + EG, W + GC, ML, EG
Graphite	W + ta, W + sl, W + am + sl, W + Teepol, W + sp3, W + ls, EL, BL, W + Aerosol OT
Gypsum	EL + cac, EG + cci, EL + EG + cci, ML + cac, AA, ML + EG + EL + cac, EG + cac, EG + stc, EG + coc, BI, EG + EL + sci
Gypsum (raw)	W + pci, W + Aerosol OT, EL + cac, EG + cci, ML
Iron	W + GC, CN, BL, W + EG, EL, W + Lissapol NX, W + EG + sp3, CL, CH, W + Triton X-100, W + sp4
Kaolin	W + am, W + ls, W + sp3, W + hc, W + sp4, W + sk6 + sca, W + so, W + sh, W + scaW + spa, W + sp6
Magnesium carbonate	W + sp4, W + sp6, ML, EL, W + am, CN, EG + cac, EG + stc, EG + coc
Magnesium oxide	BI, EG, ML
Magnesium silicates	W + sp3, W + sk6, W + sca, W + sp4, ML
Marl	W + sp4, W + sk6, W + sk6 + sca
Mica	W + sp4, W + sp6
Milk powder	BI + DP, ON, BI, AA
Pigments	W + Lissapol NX, W + pci, W + EG, W + sp4, W + Aerosol OT, PI, CL, CN
Polyvinylchloride	W + ta, W + sp3, W + sl, EG, PI + sl, BI
Portland cement	OI, BL, CL, CN, CN + AA, EG, EL + cac, EL + stc, EG + cac, EL, BI, ML, PI
Potato starch	BI, CN, BI + DP
Puzzolana	W + sp4
Quartz	W + Lissapol NX, W + sp4, EL + sp3, W + sp6, XL, W + so, W + EL, W + sp3, W + sp4 + Sterox, W + sh, W + Triton X-100
Raw meal	CL, CL + AA, BI, W + sp4
Sand, sandstone	W + CL, W + CN, EL + BP, W + sp3, W + sp4
Silicates	W + sp4, W + EL, W + GL, W + EG + sp3, W + sp4 + sp6 + so
Silicon	W + Cetrimide, W + Dispersol T, W + sp6, EL
Silicon carbide	BL, ML + Chelaplex III, W + Tween 20, W + sk6, W + sk6 + sca, W + EG + sp3
Silicon dioxide	W + sp6, W + Triton X-100, W + XL, W + EL
Slag	W, PI, W + sp4
Soil	W + sp4, W + EG, W + so, BP + EL
Starch	W + sp6, BI, PI, DP, BP + EL, BI + DP, CL, EL, ML, GC, AA
Steatite	W + sk6, W + sk6 + pca, W + sp4
Steel	W + EG, W + EG + coc, W + Lissapol NX
Sugar	BI, BI + DP, DP, AA, CN, PI
Talcum	W + sp4, W + sp6
Tin	BL, BI, BI + BL
Tin dioxide	W + sp4, W + sci, W + sk6, W + sk6 + sca
Titanium	W + Lissapol NX, W + sp4, W + sp6
Titanium carbide	W + sp4, W + Daxad 30
Titanium dioxide	W + EL, EL, W + sk6 + ph, W + EG, W + Daxad 30, W + Dispersol T, W + sp4, W + sp6, CN, CL + AA, ML, EG, W + GC, XL, W + Lissapol NX
Tuff	W + so, W + am
Tungsten	W + Renex 648, GC, EL, AC, ML, W + EG, W + GC, BL, W + GC + sp6, W + Triton X-100, EG + cac, EG + stc, EG + coc
Tungsten carbide	W + sp6, W + EG, EG + cac, EG + stc, EG + coc
Tungsten oxide	W + sp4, W + sp6, W + EL, CN, BL, W + GC, BL + EL, CL

Wheat flour	CN, EL, DP, BI, BI + DP, PM
Zinc	W + sp6, W + sp3, EL, BL, AC, CN, CL, EG + cac, BI
Zinc oxide	W + sp3, W + sp4, W + sp6, W + sk6, W + Tamol SN, W + GC, BL, EL
Zirconium	ML, W + sp4, W + sk6, ML, BI, W + ML, W + EL
Zirconium dioxide	W + GC, Woa, W + sp4, W + sk6, W + sp6
Zirconium silicate	W + sp4, W + sk6 + sca, W + EL, W + Triton X-100

Liquids

AA	Isoamylalcohol
AC	Acetone
BA	*n*-Butylamine
BI	Isobutanol
BL	*n*-Butanol
BN	*n*-Butane
BP	Butylphthalate
CH	Cyclohexane
CL	Cyclohexanol
CN	Cyclohexanone
DP	Diethylphthalate
EG	Ethyleneglycol
EL	Ethanol
ET	Ethylene
GC	Glycerol
GL	Glycol
HN	*n*-Hexane
ML	Methanol
OI	Isooctane
ON	*n*-Octanol
PI	Isopropanol
PL	Petrol
PM	Petroleum
TC	Carbon tetrachloride
W	Water
XL	Xylene

For more details, see in Bernhardt.[13]

Dispersing Aids

ac	Aluminum chloride
am	Ammonia
as	Aerosol OT
cac	Calcium chloride
cci	Cobalt citrate
coc	Cobalt chloride
hc	HCl
ls	Lignin sulfonate
ns	Naphthalene stearosulfonic acid
oa	Oleic acid
pc	Potassium chloride
pca	Potassium carbonate
pci	Potassium citrate
ph	Potassium hydroxide
sas	Sodium alkylsulfonate
sca	Sodium carbonate
sci	Sodium citrate
sh	Sodium hydroxide
sk6	Sodium/potassium hexametaphosphate
sl	Sodium linoleate
so	Sodium oxalate
sp3	Sodium triphosphate
sp4	Sodium tetrapyrophosphate
sp6	Sodium hexametaphosphate (Calgon)
spa	Sodium polyacrylate
st	Sodium tartrate
stc	Strontium chloride
ta	Tannic acid

Sieve analysis is used to obtain the particle size distribution of a solid material by determining the amount of powder retained on a series of sieves with different sized apertures. A sample is added to the top of a nest of sieves arranged in decreasing size from top to bottom. As the sieves are vibrated, the sample is segregated onto the different sized sieves. The weight of sample retained on each sieve is then used to determine the particle size distribution as well as the mean diameter of the sample.

1 INTRODUCTION

The use of sieves is the oldest and most common technique used for particle size analysis. It is generally considered to be one of the most simple, reproducible, and inexpensive methods available. Sieving can be performed on particles ranging in size from 5 μm to 125 mm. One of the main disadvantages of sieve analysis is the effect of particle shape on results. Sieving measures the smallest diameter that can pass through the opening. With irregular-shaped particles, comparison between particle size methods can be difficult. Even though comparisons of methods are not always necessary, it is often useful to obtain information about particles using several techniques based on different principles.

2 THEORY AND OPERATING PRINCIPLES

Sieve analysis is performed by segregating particles into different sized fractions on a series of sieves. The sample is placed on a nest of sieves with mesh openings decreasing in size from top to bottom. The sieves are then vibrated causing the sample to fall through the openings to a series of fractions on the individual sieves. The amount of material retained on each sieve is used to calculate the particle size distribution of the sample.[1–3]

3 METHOD DESCRIPTION

3.1 Procedures

Because sieving is used for many types of materials, it is impossible to specify a single procedure. Materials vary in size, shape, density, moisture content, cohesiveness, attritability, and so on. Therefore, general procedures for dry and wet sieving are given as guidelines. American Society for Testing and Materials (ASTM) standard methods can be referenced for information on a specific type of sample.[2]

3.1.1 Dry Sieving

The sieving procedure involves four basic steps: (1) sieve selection and set-up, (2) addition of sample, (3) sample fractionation, and (4) weighing retained fractions.[2]

3.1.1.1 Sieve Selection and Set-up Sieves are selected based on the size of the material to be characterized. The number of sieves should be minimized but give an accurate representation of the particle size distribution of the material. The sieves should be nested in a vertical stack with the coarsest sieve at the top and the solid pan at the bottom.

3.1.1.2 Addition of Sample The representative sample is dried to constant weight, when possible, and weighed to an accuracy of 0.1%. The weighed sample is then placed on the top sieve and covered.

3.1.1.3 Sample Fractionation The nest of sieves is shaken by vibration, manually, or with air pulses of sonic frequency for a specified time. A satisfactory ending time is reached when an additional one minute of sieving does not change the weight on the sieves by more than 1%.

3.1.1.4 Weighing Retained Fractions The material on each sieve is weighed to determine the amount in each particle size fraction. For small sample sizes, the material should not be removed from the sieve. The weight in each particle size fraction can be determined by difference

between the ending weight of the sieve with the sample fraction and the tare weight of the sieve.

3.1.2 Wet Sieving

Wet sieving is similar to dry, however, liquid which does not dissolve the material is continually added. The wet sieving process is particularly beneficial for separation of fine particles by eliminating electrostatic and surface forces hindering particle passage under dry conditions. Typically, wet sieving is used for materials originally suspended in a liquid or for powders that agglomerate during dry sieving. Several disadvantages of wet sieving include difficulty in obtaining accurate weight measurements, error due to swelling of particles, and increased time required for drying before weighing.

Several techniques for wet sieving have been found to be effective. In general, the sample is dispersed in a liquid and placed on the sieves. Additional liquid is then added to the residue on the sieves. Acceleration of the rate of the particles moving through the sieves is possible by placing the sieves on a vibrating apparatus and/or applying vacuum to the sieves.[1,2]

An automated wet sieving instrument has also been developed. Particles are initially placed on the finest sieves and fluidized by water. The particles that pass through the sieve are moved to a filter and weighed. After the weight remaining on the sieve has stabilized, the next larger sieve is brought into use. The procedure is continued for a series of sieves. The individual weights are then converted to weight percent data and printed.[4]

3.2 Sample Preparation

Accurate sampling is a prerequisite for reliable sieve analysis. The primary cause of inconsistencies in test results is in not obtaining a sample that is representative of the entire material. Because of the wide range of materials characterized by the sieve method, it is not possible to specify a single method of sampling. Sampling should be based upon the type and form of material. One problem that occurs is segregation of particles within the sample. During transfer of material, either in a small container or railroad car, the particles tend to segregate. In ideal circumstances, the material should be well mixed and a core sample taken. If the sample quantity is small enough, it may be reduced to test sample size using a sample splitter or riffler.[2]

3.3 Apparatus

Sieve measurements are performed with minimal equipment. The apparatus is made up of a balance, set of sieves, and possibly a mechanical shaker.[1,2] The balance should be accurate to 0.1% of the sample weight.

Table 1 Standard sieve sizes

Mesh number	Sieve aperture (mm)	Mesh number	Sieve aperture (μm)
3.5	5.6	40	425
4	4.75	45	355
5	4.00	50	300
6	3.35	60	250
7	2.80	70	212
8	2.36	80	180
10	2.00	100	150
12	1.70	120	125
14	1.40	140	106
16	1.18	170	90
18	1.00	200	75
20	850	230	63
25	710	270	53
30	600	325	45
35	500	400	38

The sieves should be chosen based upon the particle size distribution and sample quantity.

A typical sieve is a shallow pan with a wire mesh bottom or an electroformed grid. Sieves are available ranging in size from 5 μm to 125 mm. However, sieves are sometimes referred to by mesh size. Mesh is the nominal number of apertures. Table 1 gives details of the relationship between mesh size and aperture. Sieves used for sieve analysis are standardized according to ASTM E11 for woven wire mesh sieves and ASTM E161 for electroformed sieves.[1,2]

Woven wire sieves have square openings and are sturdier and less expensive than electroformed sieves. Electroformed or precision sieves have special mesh made by electrodeposition of nickel rather than weaving of wire. The conical hole structure reduces particle entrapment allowing for sharper cuts in sizing. Typically, all openings in an electroformed mesh will be identical in size. These openings are either round, square or rectangular. Electroformed sieves are typically used in the very fine particle range (5–40 μm).

Several types of mechanical sieve shaker are available. One type simulates hand sieving using a circular motion combined with a tapping motion. Another type uses electromagnetically induced high speed short stroke vibrations to agitate the sample causing it to flow through the sieve. A third type uses air pulses of sonic frequency to shake the sieves.

For wet sieving, the dry sieving apparatus can be modified by adding a vacuum pump.[1,2] In addition, companies, such as Micromeritics, have developed automated wet sieving methods. Particle size separation is achieved in an oscillating and periodically advancing rotor containing sieves of various meshes.[4]

4 INTERPRETATION OF RESULTS

4.1 Calculations

The weight of material retained on each sieve and the weight of the original test sample are used to calculate percentages. Results are normally reported in the form of percentages, not actual weights. These data are then used to calculate mean diameters, commonly referred to as average particle size. Midpoint diameters cannot be calculated for the smallest and largest fractions since the smallest and largest particle diameters are not known.

The arithmetic mean is defined as the sum of particles in a particular interval (n_i) with midpoint diameter (d_i) divided by the total number of particles (Equation 1):[3]

$$\text{Arithmetic mean diameter} = \frac{\sum n_i d_i}{\sum n_i} \qquad (1)$$

The geometric mean diameter (Equation 2) is the logarithmic equivalent of the arithmetic average:[3]

$$\log \text{geometric mean diameter} = \frac{\sum n_i \log d_i}{\sum n_i} \qquad (2)$$

In sieving, these data can also be reported as mass mean diameter or geometric mass mean diameter. The mass diameters are calculated based upon the weight of the sample rather than number of particles.

4.2 Data Representation

Particle size distribution data are presented in both tabular and graphical formats. The tabular data show the amount of material in each of the measured fractions. In addition, cumulative percent smaller than (and larger than) are often reported. An example of tabular data is presented in Table 2. These data are then graphed and used to determine the mean particle size of the material. Other fractiles, such as 10% or 90% can also be determined using this method.

The weight percent in each fraction is shown graphically in Figure 1. The weight percent is shown as a function of the midpoint diameter of the fraction given in Table 2. For example, 18% of the material is in the 40–80 μm fraction, meaning 18% has been retained on the 40 μm sieve. In the graph, this 18% value is plotted versus a midpoint particle diameter of 60 μm. The data shown in Figure 1 indicate that the particles are skewed toward the smaller sized particles.

A second type of graph commonly used in particle size testing is shown in Figure 2. This graph shows the amount of material less than a given particle diameter. For a normal distribution, a straight line can be obtained when the particle size on a linear axis is presented on a cumulative probability scale. The cumulative distribution

Table 2 Tabular representation of sieve particle size data

Diameter range, (μm)	Weight in fraction	Percent in fraction	Cumulative percent smaller than (largest size)
0–20	0.40	1.00	1.00
20–40	6.40	16.00	17.00
40–80	7.20	18.00	35.00
80–120	6.00	15.00	50.00
120–160	5.00	12.50	62.50
160–200	4.00	10.00	72.50
200–220	3.20	8.00	80.50
220–240	2.70	6.75	87.25
240–280	1.80	4.50	91.75
280–320	1.40	3.50	95.25
320–360	1.00	2.50	97.75
360–400	0.50	1.25	99.00
400–420	0.40	1.00	100.00
>420	0.00	0.00	100.00

Figure 1 Amount of material as a function of particle size fraction.

Figure 2 Cumulative percent less than graph.

data would then be symmetric at the 50% point. The arithmetic mean corresponds to the diameter at the 50% point.

The skewed data can be treated as a straight line if the arithmetic diameter scale is replaced with a logarithmic scale. Figure 3 illustrates the skewed data plotted on a log scale. To determine the geometric mean diameter, the diameter can be plotted as a function of cumulative weight percent less than using log-probability paper. The particle diameter extrapolated at the 50% value on the probability scale is the geometric mean diameter.

Graphical data representation is also useful in comparing samples. For example, Figure 4 shows three samples with the same mean diameter, but different types of distributions. The slope of the line is a measure of the breadth of the particle size distribution.[3]

Figure 3 Use of logarithmic scale to linearize skewed data.

Figure 4 Types of particle size distribution.

5 EFFECT OF PARTICLE SHAPE

Particle size data are based on the assumption that the particles being analyzed are spheres with uniform density. However, many samples analyzed for particle size distribution are not spherical in particle shape. Particle shape features cause different dimensional response characteristics depending upon the measuring instrument. Because of the complexity of the problem, only limited success has been made in quantifying the effect of particle shape on particle size analyzes. Since the diameter of a nonspherical particle is based upon a measured geometric parameter, the distribution of particle sizes will shift depending upon the parameter measured. The effect of shape on the particle size distribution is minimized if the shape distribution is small relative to the particle size distribution. If the particles are close to the same size, any change in shape will broaden the measured size distribution.

Particle shape is an important parameter in describing differences in results from various particle size methods. For example, comparisons have shown differences in results from sieving and laser light diffraction to be a function of particle shape.[5–8] One of the most significant differences between laser light diffraction and sieving for particle size determination is the dimension of the particle measured. Light diffraction measures an average of all dimensions of the particle. With sieving, the measurement is based on the smallest diameter that can pass through the opening. With irregularly shaped particles this difference results in higher particle size measurements with laser light scattering than sieving.

Because of differences in particle size measurements as a function of particle shape, instruments are now being used to calculate particle shape factors.[9] Sieves are also being used to determine particle shape distribution by measuring the rate at which particles pass through a stack of identical sieves.[10]

The determination methods of the surface area and pore size distribution (PSD) of a solid have been extensively described. The surface area and PSD are important as the basic properties for a powder and porous material. Nowadays the surface area and PSD are easily obtained by an automatic measuring instrument. However, there is no method which covers the complete range of a specific surface area and a pore size. All of the methods have their limits of measurement. In many cases the definitions of the surface area and pore size in each method differ from one another. The features and principles of the methods have been discussed mainly in order to select an appropriate method and to analyze data exactly.

1 INTRODUCTION

Determination of the surface area is important for characterization of solids, especially finely divided particles and porous materials. These materials have high specific surface areas, so the surface and interface phenomena (adsorption, adhesion, aggregation, chemical reaction and dispersion in liquids) are governed by the surface area. The determination of the surface area is necessary to understand such surface and interface phenomena on solids, and to control surface properties of solids. The measurement of the surface area is performed in various industrial fields: ceramics, pigments, fillers, catalysts, electronic materials, building materials, adsorbents, food materials, cosmetics, medicine, and so on. Several methods for determining the surface area are described in this article; however it is noticed that the definition of surface area differs from one method to another. Therefore the researcher should understand the principles of the determination methods and select an appropriate method.

Determination of the PSD of porous solids is important for porous structure analyses. Porous structures affect adsorption property, permeability, diffusion of gases and ions, thermal conductivity, strength, and so on. Many determination methods of the PSD have been proposed, and commercial apparatus is available. However, the researcher should note the following: most methods assume the simple pore model, for example the cylindrical pore model, but this is quite different from real pore structures; and all the methods have a lower and upper limit of detection for the pore size. In analogy with surface area determination, the selection or combination of methods and the understanding of methodology are important. Studies about the determination of the PSD are still being carried out. The current topics are available in the *Proceedings of the Characterization of Porous Solids*.[1–4]

2 DETERMINATION OF SURFACE AREA

2.1 Gas Adsorption Method

The determination of the surface area by gas adsorption is one of the most reliable methods, and is widely used for powders and porous materials. It is necessary for the adsorption method to estimate monolayer capacity (V_m) of an adsorbate and cross-sectional area (σ) of an adsorbed molecule. The specific surface area (S; the surface area of 1 g of the solid) is given by Equation (1):

$$S = V_m \sigma N_A \quad (1)$$

where V_m is expressed in moles per gram of the solid and N_A is the Avogadro number. Monolayer capacity is usually estimated from the adsorption isotherm by the

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

Brunauer–Emmet–Teller (BET) method.[5] The BET equation is shown in Equation (2):

$$V = V_m \frac{CX}{(1-X)(1-X+CX)} \tag{2}$$

where V is the amount of gas adsorbed, C is a constant value and X is the relative pressure: P/P_0 (P, equilibrium pressure and P_0, saturated vapor pressure). Usually Equation (2) can be rewritten for plotting experimental data as Equation (3):

$$\frac{X}{V(1-X)} = \frac{1}{V_m C} + \frac{(C-1)X}{V_m C} \tag{3}$$

The plot of $X/V(1-X)$ against X is called the BET plot, which is usually linear in the range of $0.05 < X < 0.35$. It should be noted that the relative pressure range in which the BET plot shows linearity depends on the kind of adsorbates and solids. The value of V_m and C are calculated from the slope $(C-1)/V_m C$ and intercept $1/V_m C$ of the BET plot. The adsorption isotherm of nitrogen and the BET plot are shown in Figure 1. The constant C is represented by Equation (4):

$$C \cong \exp \frac{Q_1 - Q_L}{RT} \tag{4}$$

where Q_1 is the isosteric heat of adsorption of molecules in the first layer and Q_L is the heat of condensation of the liquid adsorbate. The constant C represents the interaction between the adsorptive molecule and solid surface qualitatively. Thus the shape of the adsorption isotherm depends on the constant C. The adsorption isotherms deduced by the BET equation are shown in Figure 2.

The cross-sectional areas (σ) of adsorbed molecules have been calculated by various methods. Usually the σ-value is estimated from the liquid density (d) of the adsorbate at the working temperature, using Equation (5):[6]

$$\sigma = F \left(\frac{M}{N_A d} \right)^{\frac{2}{3}} \tag{5}$$

where F is the packing factor and M is the molecular weight of the adsorbate. The packing factor (F) is determined by the coordination number of adsorbed molecules on solid surfaces and in the adsorbed layer.[7] If the liquid structure of the adsorbate is the closest packing structure with 12 nearest neighbors, and the adsorptive molecules are adsorbed on the surface with 6 nearest neighbors in the close-packed hexagonal arrangement, the value of F is 1.081. Usually the adsorption gas used for the surface area determination is nitrogen, because nitrogen molecules can form a monolayer at 77 K on various solids. The σ-value for the nitrogen molecule is 0.162 nm^2. In the case of nitrogen adsorption, if V_m is

n-C_6H_{14}	0.562

in milliliters at standard temperature and pressure per gram, the specific surface area can be estimated using Equation (6):

$$S(m^2\,g^{-1}) = 4.35\,V_m \tag{6}$$

McClellan and Harnsberger[8] have produced a table of the σ-values for about 106 compounds. The average σ-values of several molecules calculated from adsorption data are summarized in Table 1. Generally the surface areas determined by nitrogen adsorption differ from those estimated from adsorption of other gases. Several reasons for these differences are given: change in the σ-value due to orientation of the adsorbate molecule, the validity of the BET equation, and so on. One of the reasons is attributed to the difference in the accessibility of the adsorptive molecule to surface geometry. Consequently the surface areas depend on the size of probe molecules. Avnir et al.[9] have derived the fractal dimension (D) of solid surfaces from the adsorption of various gases on solid surfaces.

Usually nitrogen gas is used to measure the surface area. However, for the measurement of very small surface areas, adsorption of krypton[10–13] or xenon[14–16] gases at low temperature (77 K or 83 K) are used. The vapor pressure of these gases at 77 K is very low, so the correction of the vapor pressure is required for the thermal transpiration effect.[17]

A lot of commercial apparatus is available for surface area determination by gas adsorption measurement. This apparatus is classified into three categories: volumetric method, carrier gas method (dynamic method) and gravimetric method. Adsorption measurement by quartz crystal microbalance (QCM)[18,19] or surface acoustic wave (SAW)[20–22] devices are some of the new techniques for surface area determination. The principle of these techniques is based on the change in oscillation frequency of the quartz or the SAW oscillator, according to the change in surface mass density. The relationship between the change in oscillation frequency (Δf) of the oscillator and the change in surface mass density (ΔW) using the quartz oscillator is shown in Equation (7):

$$\Delta f = -f_0^2 \frac{\Delta W}{NA\rho} \tag{7}$$

where f_0 is the parent frequency, N is the frequency constant for AT-cut quartz (1.67×10^6 Hz mm), A is the area of the electrode, and ρ is the density of quartz ($2.648\,g\,cm^{-3}$). The sensitivity of a 10 MHz QCM is $5\,ng\,cm^{-2}$. The QCMs or SAW devices are capable of measuring nitrogen adsorption on thin films. Commercial volumetric or gravimetric adsorption apparatus cannot obtain nitrogen adsorption data of such low surface area materials. These techniques are applicable to estimate the pore structure analysis by gas adsorption (see section 4.1).

2.2 Liquid Adsorption Method

The principle of the determination of surface area by liquid adsorption is the same as that by gas adsorption. Dyes[23–28] or fatty acids[29–31] in solution are frequently used as a probe molecule for the surface area determination. The liquid adsorption method is easy to operate and does not need special apparatus compared to the gas adsorption method. However it is necessary to estimate the cross-sectional area of an adsorptive molecule and the effect of solvent. Because a cross-sectional area of an adsorptive molecule depends on the configuration of an adsorbed molecule, competitive adsorption of adsorptive molecules between solvent molecules occurs. So the solutes (adsorptives) and solvents should be carefully selected for the sample solid. The liquid adsorption isotherm is represented by a plot of the amount of adsorbed vs the equilibrium concentration of the adsorptive. Several equations for the liquid adsorption isotherm have been proposed: the Henry equation, the Langmuir equation, the Frumukin equation and the Freundlich equation. The Langmuir equation is frequently used to determine the monolayer capacity. The equation is expressed by Equation (8):

$$V = \frac{AV_mC}{1 + AC} \tag{8}$$

where A is a constant. The expression for plotting experimental data is given by Equation (9):

$$\frac{C}{V} = \frac{1}{V_mA} + \frac{C}{V_m} \tag{9}$$

The monolayer capacity is obtained from the slope of the plot of C/V against C. Figure 3 shows adsorption isotherms of several dyes on charcoal.[24] The cross-sectional areas of dye molecules[32] are shown in Table 2. In the case of dye adsorption, the formation of molecular aggregates in high concentration and the effect of

Figure 3 Adsorption isotherms for dyes on activated charcoal at 21 °C: (●) Methylene Blue; (○) Brilliant Basic Red; ( ) Victoria Pure Lake Blue BO. [Reproduced by permission of The Royal Society of Chemistry from C.H. Giles, A.P. D'Silva, *Trans. Faraday. Soc.*, **65**, 1943–1951 (1969).]

Table 2 Cross-sectional area and λ_{max} of dyes

Dye	Cross-sectional area (nm^2)	λ_{max} (nm)
Methylene Blue	1.20	661
Crystal Violet	2.25	588
Victoria Pure Lake Blue BO	2.75	619
Orange II	1.20	483

pH on adsorption should be noted. The concentration of dye solution is determined from the measurement of absorbance of the solution by ultraviolet/visible spectrometer. The dye adsorption method is applicable to measure low surface area ($\sim 0.01\,m^2\,g^{-1}$). However, accessibility of dye molecules to internal surfaces should be considered because the size of dye molecules is large compared to that of gas molecules, which are usually used as probe molecules for surface area determination.

In the case of fatty acid adsorption, steric acid in organic solution (ethanol, hexane, and benzene) is frequently used. The organic solvents should be dehydrated. The cross-sectional area of steric acid is assumed to be $0.208\,nm^2$ if molecules of steric acid are adsorbed perpendicular to the solid surfaces. The concentration of steric acid is estimated by the titration method.

The direct adsorption of ethylene glycol is used to determine the surface area of clay minerals.[28,33–35] The cross-sectional area of an ethylene glycol molecule is assumed to be $0.224\,nm^2$.

2.3 Permeametry

Surface area determination by permeametry is used for powder materials. This method is characterized by simple apparatus, easy operation and rapid measurement compared to the other method. Permeametry is based on fluid flow through a packed powder bed (porous media). The specific surface area is calculated from the Kozeny–Carman equation, shown in Equation (10):

$$S_w = \frac{1}{\rho}\left\{\left(\frac{\Delta P t A}{k\eta L V}\right)\left(\frac{\varepsilon^3}{(1-\varepsilon)^2}\right)\right\}^{\frac{1}{2}} \tag{10}$$

where S_w is the specific surface area of the sample powder, ρ is the true density of the sample powder, ΔP is pressure drop, t is time, A is the cross-sectional area of the powder bed, k is the Kozeny constant, which is usually assumed to be 5, η is the viscosity coefficient of the fluid, L is the length of the powder bed, V is the volume of fluid passed through powder bed during time t, and ε is the porosity of the powder bed. The surface area of the powder bed can be calculated from measurement of the flow rate V/t and pressure drop ΔP. Gases and liquids can be used as the flowing fluids, however, gases (air or He gas) are usually used, rather than liquids, in order to avoid a dissolution of samples and reconstruction of the powder bed. The many equations for permeametry based on the Kozeny–Carman equation have been derived to fit the experimental procedure, and many types of apparatus have been proposed.[36–41] The Blaine apparatus and the Fischer Sub-Sieve Sizer apparatus[42] are typical for air permeametry. This apparatus is commercially available. The surface area thus obtained means the external surface area and does not include internal surface: micropores and cracks. Equation (10) is applicable only in the viscous flow condition, so this analysis is limited to coarse powder particles ($\sim 2\,\mu m$).

When the particle size of the powder bed becomes smaller ($<\sim 1\,\mu m$), the gas flow mechanism changes from viscous flow to Knudsen flow, which is controlled by the rate of molecular diffusion. Carman modified Equation (10) by considering the Knudsen flow and derived the general equations shown in Equations (11) and (12):

$$\frac{V'L}{\Delta PA} = \left(\frac{P'}{5\eta S_v^2 RT}\right)\left(\frac{\varepsilon^3}{(1-\varepsilon)^2}\right) + \left(\frac{4Z}{3}\right)\left(\frac{v}{S_v}\right)\left(\frac{\varepsilon^2}{1-\varepsilon}\right) \tag{11}$$

$$\rho S_w = S_v \tag{12}$$

where V' is the velocity (moles per second) of fluid gas, P' is the average pressure in the powder bed, Z is a constant, and v is the rate of molecular diffusion. The first term of the right-hand side is the contribution of viscous flow and the second term is that of the Knudsen flow. The plot of $V'L/\Delta PA$ vs P' should be linear. The surface area calculated from the slope of the linear line corresponds to the external surface area. However, the surface area estimated from the intercept represents the total surface area of the powder sample. The constant Z depends on

the shape of the path. The Z value is experimentally determined to be 0.45 or 0.47. Several other studies on permeametry in the Knudsen flow condition have been reported.[37,38,43,44]

2.4 Other Methods

2.4.1 Microscopic Method

If the powder samples have no pores, the specific surface area of solids is estimated from the size of the primary particle as shown in Equation (13):

$$S = \frac{K}{\rho l} \tag{13}$$

where S is the specific surface area of the solid, K is the shape factor, ρ is true density of the particle, and l is the size of the particle. If the particle shape is cubic or spherical, the constant K is 6 and l represents the edge length of the cubic particle or the diameter of the spherical particle. Usually the size of the primary particle, l, is determined using optical or electron microscopy.

2.4.2 Heat of Immersion Method

When a solid surface is immersed in liquid which does not dissolve the solid, heat which is termed the heat of immersion is evolved. Harkins and Jura[45] developed an ''absolute method'' to estimate the surface areas of powders using the measurement of heat of immersion. When the sample powder with the liquid adsorbed layer is immersed in the adsorptive liquid, the heat of immersion is attributed to the total surface energy of the adsorptive liquid. The surface area (S) is represented by Equation (14):

$$S = \frac{Q}{h_{\mathrm{L}}} \tag{14}$$

where Q is the heat of immersion and h_{L} is the enthalpy per unit surface area of the adsorption liquid. In the case of water, a two-molecule-thick adsorbed layer on a solid surface is sufficient to measure[46] and h_{L} is 118 erg m^{-2}.

3 CLASSIFICATION OF PORE SIZES AND PORE STRUCTURE

Pores are classified into three types, based on their sizes, according to the IUPAC recommendation:[47]

Macropores	$d(w) > 50\,\mathrm{nm}$
Mesopores	$2\,\mathrm{nm} < d(w) < 50\,\mathrm{nm}$
Micropores	$d(w) < 2\,\mathrm{nm}$

where d and w mean a pore diameter and a pore width, respectively. Many methods for determing the PSD of porous materials have been proposed. However, there is no experimental technique covering the whole range of pore size. Hence, it is important to choose methods appropriate for the pore size. It should be noticed that each method has a detection limit for the pore size. The applicable range of pore size for PSD analysis methods described in this chapter is shown in Figure 4.

Figure 5 shows a model of pores in a solid. The pore structure is mainly classified into two categories: closed pores (a) and open pores (b–h). The open pores consist of several types: through pores (b) are open at two ends, blind pores (c) are open only at one end, independent pores (b), (c) do not connect with other pores and crossing pores (d) connect with other pores. From the viewpoint of pore shape, pores are classified as follows: cylindrical pores (e), conical pores (f), ink-bottle pores (g), slit pores (h), and so on. The consideration of the origin of pores is useful for the understanding of pore structure. The pores in zeolite, which is well-known as a

Figure 4 Applicable range of pore size to various pore analysis methods.

Figure 5 Models of a pore.

molecular sieve and catalyst, originate from the crystal structure. The slit pore in layered materials such as clay minerals and graphite is in this category. These pores are characterized by a regular structure. Some pores can be prepared by the removal of substances dispersed in a solid beforehand. Porous silica glass is prepared by the dissolution of a separated $Na_2O-B_2O_3$ phase in the SiO_2 matrix. The mesoporous silica MCM-41 is prepared by the micelle template.[48] Silica gel containing organic polymer can form pores by calcination. The size and structure of pores originated from the removal of additives in a solid depend on the dispersion condition and size of additives. The aggregation of small particles forms voids (pores) between the particles. These pore structures depend on the particle size and its distribution, particle shape and packing structure.[49] The sintered body and silica gel are attributed to this structure.

4 DETERMINATION OF MACROPORE AND MESOPORE SIZE

4.1 Gas Adsorption Method

4.1.1 Capillary Condensation Method

Generally the adsorption isotherm of gas on a mesoporous solid shows the Type IV isotherm in the IUPAC classification of adsorption isotherms.[47] The Type IV isotherm is shown in Figure 6. The adsorption isotherms on a mesoporous solid show a steep increase in the amount adsorbed due to capillary condensation, and a steep decrease in the adsorbed amount due to capillary evaporation. Consequently, the adsorption isotherm has a hysteresis loop. The capillary condensation method for the determination of PSDs is based on the relationship between the pressure at which capillary condensation occurs and the pore radius. This relationship is represented by the well-known Kelvin equation, shown in Equation (15):

$$r_k = \frac{-2\gamma V_m \cos\theta}{RT\ln(P/P_0)} \tag{15}$$

where r_k is the Kelvin radius, and γ and V_m are surface tension and molar volume of the condensate, respectively, T is a measuring temperature, θ is a contact angle between the condensate and the pore wall, and P/P_0 is the relative pressure at which capillary condensation occurs. Usually θ is assumed to be zero, so Equation (15) is simplified to Equation (16):

$$r_k = \frac{-2\gamma V_m}{RT\ln(P/P_0)} \tag{16}$$

When capillary condensation occurs, the thickness of a layer already adsorbed on the pore walls is given by t. Consequently the pore radius is given by Equation (17):

$$r_p = r_k + t \tag{17}$$

In the case of nitrogen adsorption, many studies on the thickness of the adsorbed layer have been reported.[50–57] Several equations for the relationship between the thickness of the adsorbed layer and relative pressure have been proposed for computation. Dollimore and Heal[58] recommended the use of Equation (18):

$$t\,(\text{nm}) = 0.35\left(\frac{-5}{\ln(P/P_0)}\right)^{\frac{1}{3}} \tag{18}$$

A number of calculation methods for the determination of PSDs based on the Kelvin equation (e.g. Barret–Joyner–Halenda (BJH) method, Dollimore–Heal (DH) method) have been proposed;[50,59–64] however, the principle of the computation procedure is almost the same. The calculation of PSDs is performed according to the following concept. The amount (ΔV) decreased in a desorption step is represented by the sum of the amount (ΔV_c) of capillary evaporation, and the amount (ΔV_m) of multilayer desorption from the pores in which capillary evaporation has already occurred, as shown in Equation (19):

$$\Delta V = \Delta V_c + \Delta V_m \tag{19}$$

The capillary condensation method is widely used for the determination of PSDs of mesoporous solids, and automatic measuring apparatus is commercially available. However, it should be noticed that this method has several

Figure 6 Model of Type IV adsorption isotherm.

problems. First, the simplified pore model (cylindrical pore or slit-shaped pore) is assumed. It is clear that this model is quite different from real porous structures. Second, as mentioned above, the adsorption isotherm on mesoporous solid shows a hysteresis loop. It should be noticed whether the calculation is performed on the adsorption or desorption branch of the hysteresis loop. Equation (15) is adopted for analysis of the desorption branch. When the adsorption branch is used for analysis, the Kelvin equation shown in Equation (20) is used:

$$r_k = \frac{-\gamma V_m}{RT \ln(P/P_0)} \tag{20}$$

This problem is very important, because the PSD depends on which branch of the hysteresis loop is used for the calculation. Further study, including the origin of the hysteresis loop, is required. The lower and upper pore size limits of the capillary condensation method are obscure. In a small pore it is expected that the physical properties of capillary condensed liquids are different from those of bulk liquids. Hence, the calculation of the pore radius by the Kelvin equation using the bulk values of surface tension and molar volume of condensates is inadequate for small pores. The criticisms on the application of the Kelvin equation in small pores have been reported.[65–72] The development of idealized mesoporous solids such as MCM-41,[48] and the progress in computer chemistry of adsorption simulation,[73,74] will be expected to refine the capillary condensation method in the small pore size region. However, the upper pore size limit depends on the accuracy of the adsorption measurement. The relationship between relative pressure and the pore radius is shown in Table 3. Clearly it is difficult to analyze macropore sizes with high precision compared with mesopore sizes.

4.1.2 Comparison Plot Method

The comparison plot method is one of the pore-structure analyses and reveals the existence of micropores and mesopores. Two kinds of comparison plots have been proposed: the t-plot developed by Lippens and de Boer[75] and the α_s-plot by Sing.[55,76] Both plots are obtained by comparison of the nitrogen adsorption isotherm on the sample with that on a standard solid. The standard solid should be equivalent to the sample solid and have no pores. In the case of the t-plot, the relationship between the relative pressure and the thickness of the adsorbed layer for the standard solid is required. The thickness (t) of the adsorbed layer of nitrogen is calculated from Equation (21):

$$t\,(\text{nm}) = \frac{0.354\,V}{V_m} \tag{21}$$

where V is the amount adsorbed, and V_m is the monolayer capacity. Standard data are shown in Table 4.[55] The t-plot of the sample is obtained by converting the relative pressure of the adsorption isotherm on the sample into the thickness of the adsorbed layer of nitrogen, according to the standard data. Models of t-plots are shown in Figure 7. When the sample has no pores, the t-plot gives a straight line. The specific surface area (S_t) is calculated from the slope of the t-plot using Equation (22):

$$S_t = \frac{1.547\,V}{t} \tag{22}$$

If the sample has mesopores, the t-plot deviates upwards from a straight line, due to capillary condensation. When

Figure 7 Model of t-plots: (a) non-porous solid; (b) mesoporous solid; (c) microporous solid.

the pore fills with the adsorbate, the slope of the t-plot is gradual. The external surface area of the sample is estimated from the slope of this part. If the sample has micropores, the t-plot again deviates downwards from a straight line, due to micropore filling. The disadvantage of the t-plot is the uncertainty of the thickness below the monolayer (<0.354 nm). The α_s-plot was developed to improve this disadvantage. The α_s-value is defined instead of the t-value, as shown in Equation (23):

$$\alpha_s = \frac{V}{V_{0.4}} \tag{23}$$

where $V_{0.4}$ is the amount adsorbed at $P/P_0 = 0.4$. Standard data are shown in Table 4.[55] The plot of V against α_s is called the α_s-plot. Basically, the interpretation of the α_s-plot is similar to that of the t-plot. The specific surface area (S_{α_s}) is represented by the slope of the α_s-plot, as shown in Equation (24):

$$S_{\alpha_s} = \frac{2.89\,V}{\alpha_s} \tag{24}$$

The α_s-plot is especially useful to determine the surface area of microporous materials.[77,78]

4.2 Mercury Porosimetry

Mercury porosimetry is based on the fact that excess pressure is required to cause the intrusion of mercury, which is the non-wetting liquid for most of the materials into the pore. The relationship between the pressure and the pore radius is expressed by the Washburn equation shown in Equation (25):

$$r = \frac{-2\gamma\cos\theta}{P} \tag{25}$$

where r is the pore radius, γ is the surface tension of mercury, θ is the contact angle between mercury and the pore wall, and P is the excess pressure. The surface tension of mercury is 485 dyn cm^{-2} and θ is usually assumed to be 140°. So Equation (25) can be expressed by Equation (26):

$$r\,(\mu\text{m}) = \frac{107.7}{P\,(\text{psi})} \tag{26}$$

One feature of mercury porosimetry is that it is capable of estimating the size of a wide range of pores (from mesopores to macropores). It is especially useful for determining the macropore size range, because there are few methods applicable to analysis of macropores. The lower-limit pore size and upper-limit pore size depend on the pressures which the apparatus can achieve. Nowadays commercially available apparatus can work at 60 000 psi, so the measurable pore size range is between 1.8 nm and 108 μm (if the minimum pressure is 1 psi). Usually a value of 140° as the contact angle is used for computation; however, it is predicted that the contact angle is affected by the surface chemical composition and the surface roughness.[79] The contact angle at atmospheric pressure will differ from that at high pressures. A change in contact angle by 10° from 140° causes a change in pore size of 16%. The problem of contact angle should be discussed in the future. Destruction or deformation of the sample is caused by compression. Reversible deformation should be corrected. However, irreversible deformation or destruction is seriously affected by the PSDs. The sample which amalgamates with mercury is unsuitable for this method. Contamination by amalgam causes a change in contact angle and surface tension of mercury. Intrusion–extrusion curves of mercury porosimetry are shown in Figure 8.[80] Intrusion–extrusion curves frequently display a hysteresis loop. Several reasons for the occurrence of the hysteresis loop have been proposed: the difference in contact angles at intrusion and

Figure 8 Intrusion–extrusion curves for a porous glass sample. [Reproduced by permission of Academic Press from S. Lowell, J.E. Shields, *J. Colloid Interface Sci.*, **83**, 273–298 (1981).]

extrusion;[80,81] the geometrical shape of individual pores (e.g. ''ink-bottle'' type pore); and the network effect of pores. The morphology[82] and pore connectivity[83] have been estimated from the hysteresis loop.

If a non-wetting liquid is used for the sample solids, the principle of mercury porosimetry can be applied to other liquids. Recently, water porosimetry for hydrophobic materials has been attempted.[84]

4.3 Thermoporometry

Thermoporometry is based on calorimetry of the liquid–solid transition of a condensate confined in pores. It is well known that the freezing and melting points of liquids confined in pores decrease with decrease in the pore size. Brun et al.[85] developed a method of determining PSDs from a solidification thermogram by means of theoretical relationships. The relationship between the depression of the freezing or melting point (ΔT) of water and pore radius (r_p) is given by Equation (27) for freezing and Equation (28) for melting:

$$r_p(\text{nm}) = -\left(\frac{64.67}{\Delta T} + 0.57\right) \quad (27)$$

$$r_p(\text{nm}) = -\left(\frac{32.33}{\Delta T} + 0.68\right) \quad (28)$$

The pore volume is estimated from the apparent energy (W_a) of freezing or melting of water. These values are obtained for freezing from Equation (29) and for melting from Equation (30):

$$W_a(\text{J g}^{-1}) = -5.56 \times 10^{-2}\Delta T^2 - 7.43\Delta T - 332 \quad (29)$$

$$W_a(\text{J g}^{-1}) = -0.155\Delta T^2 - 11.39\Delta T - 332 \quad (30)$$

Usually water is used as the condensate in pores, because water shows a larger latent heat at the liquid–solid transition as compared to other condensates. However, some organic liquids used as condensate for thermoporometry have been reported: benzene,[85] undecane,[86,87] decane,[88] and paranitrophenol.[89] These organic liquids are useful for the measurement of the hydrophobic materials and overambient measurements.[89] The dependence of melting points of water and benzene on pore radius is shown in Figure 9.[85] The advantage of thermoporometry is that pore analysis can be performed in wet environments. Thermoporometry is appropriate for the analysis of wet gels[88,90] and polymeric ultrafiltration (UF) membranes.[91–93] The pore shape or structure of aggregates of these materials changes with the drying process. Thermoporometry can be used for rigid porous materials.[94,95] Several methods of determining PSDs based on the liquid–solid transition have been proposed.[96–99] The thermograms are obtained using a dilatometer or differential scanning calorimeter, and are measured at a slow scanning rate (0.1–1 K min^{-1}) in order to maintain equilibrium.

Figure 9 Dependence of melting points of water and benzene on pore radius. [Reproduced by permission of Elsevier Science from M. Brun, A. Lallemand, J.-F. Quinson, C. Eyraud, *Thermochim. Acta*, **21**, 59–88 (1977).]

The freezing/melting transition of water, benzene and cyclohexane confined in porous materials has been measured by ^{1}H-NMR (nuclear magnetic resonance).[100] The PSD has been derived from ^{1}H-NMR signal intensity vs temperature curves of the confined liquids in the pores. The liquid–solid transition in pores is estimated from the ^{1}H-NMR signal intensity.

4.4 Other Methods

4.4.1 X-ray Scattering Method

Porous materials have differences in electron density (solids and voids), so small-angle X-ray scattering (SAXS) occurs. The Guinier equation is represented by Equations (31) and (32):

$$I(Q) = I_0 \exp\left(\frac{-R_G^2 Q^2}{3}\right. \quad (31)$$

$$Q = \frac{4\pi \sin\theta}{\lambda} \quad (32)$$

where $I(Q)$ is the strength of scattering, I_0 is a constant, R_G is the gyration radius of the pore, Q is the scattering parameter, and λ is the wavelength of the X-ray. If the pore is spherical, the pore radius (r) is related to R_G by Equation (33):

$$R_G = \left(\frac{3}{5}\right)^{\frac{1}{2}} r \quad (33)$$

According to this method the size of closed pores can be estimated.

5 DETERMINATION OF MICROPORE SIZE

5.1 Dubinin–Radushkevich Method

The Dubinin–Radushkevich (DR) method is based on the analysis of the gas adsorption isotherm. The gas adsorption isotherm on microporous solids shows a Type I isotherm (Figure 10). The Type I isotherm is called the Langmuir type, which is frequently observed during chemisorption. However, in the case of physisorption on microporous solids, the origin of the shape of the adsorption isotherm is due to micropore filling. The micropores tend to fill with adsorbate at low relative pressures. The adsorption isotherm on the microporous solids is described by the DR equation shown in Equations (34) and (35):[101,102]

$$W = W_0 \exp\ -B\left(\frac{T}{\beta}\right)^2 \log^2\left(\frac{P_0}{P}\right) \tag{34}$$

$$E_0 = \frac{0.01915}{B^{1/2}} \tag{35}$$

where W is the volume of micropores filled at relative pressure P/P_0 and temperature T, W_0 is the total volume of micropores, B is the so-called structural constant, the parameter β is the affinity coefficient, which depends on the adsorptive [$\beta(C_6H_6) = 1$], and E_0 is the characteristic energy of adsorption. Equation (34) is rewritten for experimental use as Equation (36):

$$\log W = \log W_0 - D\log^2\left(\frac{P_0}{P}\right) \tag{36}$$

A plot of $\log W$ against $\log^2(P_0/P)$ is called a DR plot and the total volume of micropores is calculated from the intercept. A DR plot is shown in Figure 11.[103] The characteristic dimension of the micropore (x),

Figure 10 Model of Type I adsorption isotherm.

Figure 11 DR plot of adsorption of argon at 77 K on activated carbon. [Reproduced by permission of Academic Press from H. Marsh, B. Rand, *J. Colloid Interface Sci.*, **33**, 101–116 (1970).]

corresponding to the half width of the slit pore, is related to the characteristic energy of adsorption (E_0) by Equation (37):

$$x = \frac{k}{E_0} \tag{37}$$

where the value of the parameter k depends on E_0. When the value of E_0 is 22–14 kJ mol^{-1}, the value of k is 12.5–12.9 kJ nm mol^{-1}.[104] The pore size of the micropore can be calculated from Equation (37) using the DR equation.[104,105]

5.2 Horvath–Kawazoe Method

Horvath and Kawazoe[106] theoretically determined an average potential function inside the slit-shaped pore model. Equation (38) is the general expression of the Horvath–Kawazoe (HK) equation:

$$RT\ln\left(\frac{P}{P_0}\right) = \frac{K}{\sigma^4(l-2\delta)}\ \frac{\sigma^4}{3(l-\delta)^3} - \frac{\sigma^{10}}{9(l-\delta)^9} - \frac{\sigma^4}{3\delta^3} + \frac{\sigma^{10}}{9\delta^9} \tag{38}$$

where P/P_0 is the relative pressure, parameter K depends on the properties of adsorbent and adsorbate, σ is the distance between a gas atom and the surface at zero interaction energy, 2δ is the sum of the molecular diameter of adsorbed molecules and the atomic diameter of solid atoms, and l is the distance between the nuclei of the parallel layers (Figure 12). Consequently, the effective pore size (w) is given by Equation (39):

$$w = l - \delta_s \tag{39}$$

where δ_s is the diameter of solid atoms. In the case of the nitrogen adsorption in slit-shaped pore (graphite),[106] Equations (38) and (39) are given by Equations (40)

Figure 12 Model of a slit-shaped pore.

and (41):

$$\ln\left(\frac{P}{P_0}\right) = \frac{62.38}{l-0.64}\,\frac{1.859\times10^{-3}}{(l-0.32)^3} - \frac{2.7087\times10^{-7}}{(l-0.32)^9} - 0.05014 \qquad (40)$$

$$w = l - 0.34 \qquad (41)$$

where l and w are in nanometers. The effective pore sizes corresponding to the relative pressures are shown in Table 5. The HK equation has extended the other systems. Swiatkowski et al.[107] deduced the equations for benzene– and argon–carbon systems. These are shown in Equations (42) and (43), respectively:

$$\ln\left(\frac{P}{P_0}\right) = \frac{72.619}{l-2\delta}\,\frac{2.874\times10^{-3}}{(l-\delta)^3} - \frac{7.67\times10^{-7}}{(l-\delta)^9} - 0.05567 \qquad (42)$$

$$\ln\left(\frac{P}{P_0}\right) = \frac{62.38}{l-2\delta}\,\frac{1.859\times10^{-3}}{(l-\delta)^3} - \frac{2.7087\times10^{-6}}{(l-\delta)^9} - 0.05014 \qquad (43)$$

The HK equation has been extended to argon adsorption in cylindrical[108] and spherical pores[109] of zeolites.

5.3 Other Methods

5.3.1 Comparison Plot Method

The comparison plot method is described in section 4.1.2.

5.3.2 Molecular Probe Method

The molecular probe method is based on the molecular sieving abilities of micropores. The effective pore size can be estimated from the adsorption capacities of a series of molecules varying in size and shape.[110,111]

5.3.3 Nuclear Magnetic Resonance Method

The chemical shift of NMR spectra reflects the local environment of the observed nucleus. ^{129}Xe NMR of adsorbed Xe in micropores has been developed to study the local environment in pores.[112–114]

The size of particles in a suspension can be estimated by measuring the turbidity of the suspension. Turbidity measures the attenuation of a beam of light traveling through the suspension caused by the scattering and absorption of light by the particles. The amount of scattering and absorption depends on the size of the particles and their concentration in the suspension. Most of the reported applications in the literature use turbidimetry for the estimation of the particle size distribution (PSD) or an average size for particles with diameters ranging from 0.035 to 50 μm. Turbidimetric techniques are low cost, experimentally simple, fast, nondestructive and require no calibration. They are robust methods with very good reproducibility and can be used either off- or on-line, in a laboratory or a plant environment. They have been used for particle or droplet size determination in a variety of diverse systems such as latex particles, silver bromide sols and cow's milk. Most of the time common ultraviolet/visible (UV/VIS) spectrophotometers are utilized for the turbidity measurements. Certain modifications may be necessary on these instruments depending on the size of the particles. The turbidity of the suspension is measured and the size of the particles or the PSD is estimated utilizing light scattering theory. For spherical isotropic homogeneous particles and absence of multiple scattering this theory is well established. The extension to nonspherical and inhomogeneous particles is a field of active research yielding numerous publications.

A controversy existed in the literature regarding the capability of turbidimetry to provide the full PSD but has now been resolved. For polydisperse suspensions, for certain combinations of particle sizes and optical properties, the method cannot provide the full PSD, but only an average of the PSD. This limitation is simply a result of the light scattering patterns and it is expected theoretically. In some cases it can be overcome by simply altering the optical properties of the suspension (i.e. choosing the proper wavelengths for the turbidity measurements or a medium with a different refractive index to suspend the particles). To make the best use of the method and interpret the results in a meaningful way

one should be aware of this limitation and work with it. When this is done, excellent results can be achieved. The advantages of the method and a good knowledge of its capabilities make it a very robust choice for many applications. The numerous reports from the successful application of the method are a testimony to this.

1 INTRODUCTION

Turbidimetry refers to a group of techniques that utilize either turbidity measurements at different wavelengths, or a combination of measurements of turbidity and of the particle volume fraction, to estimate the size of particles in suspensions. Turbidity measures the attenuation of a beam of light when it passes through a suspension of particles. Using light scattering theory this attenuation can be theoretically related to the size and concentration of particles in the suspension if the optical properties (refractive indices of particles and medium) are known. For spherical particles and absence of multiple scattering this theory is well established. Extensions to nonspherical particles have been reported. Simple UV/VIS spectrophotometers can be modified (and in some cases used as bought) for the turbidity measurements. Wavelengths in the near-infrared (NIR) range can also be utilized. Particle sizes from the lower submicrometer range to many micrometers can be measured with the proper choice of wavelength for the turbidity measurements. Applications of turbidimetry for particle size determination have been reported mainly for particles with diameters between 0.035 and 50 μm. The simplicity of this fast, noninvasive method, its low cost, good reproducibility and the wide range of particle sizes that it covers have made it very attractive for particle size determination. Mainly owing to its simplicity, the method is robust and suitable for industrial production environments as an on-line particle size determination method.

The first attempts to use turbidimetry for particle size determination started in the 1950s. At the time workers tried to use approximation theories[1] or tabulate turbidity functions[2,3] mainly owing to a lack of powerful computing machines. Ever since, there has been an abundance of reports on the use of turbidimetric techniques for the determination of particle size in a variety of systems, such as silver bromide sols in water,[4–6] polystyrene latexes,[7,8] poly(vinyl acetate) latexes,[9–15] homogenized milk and oil-in-water emulsions,[16–18] coupler dispersions[19] and minerals.[20] A wide range of wavelengths in the UV/VIS region have been utilized for the turbidity measurements but also work in the NIR region has been reported.[6,16,17,19] The determination of particle size using on-line turbidimetry has also attracted a lot of attention.[6,9–11,15,21–24] Some of the work reported in the literature for particle size determination in polydisperse systems (full PSD or an average diameter) for different materials is given in Table 1.

A controversy in the literature[11,12,31] regarding the capability of turbidimetry to provide the full PSD has been resolved by a theoretical analysis and experimental verification reported in Kourti et al.[15,32] The results can be summarized as follows.

The capability of turbidimetric techniques to provide an average particle size or the PSD of a suspension and their sensitivity to experimental error cannot be generalized across refractive indices and particle size ranges. It depends on the optical properties of the suspension and the size of the particles relative to the wavelength and conclusions cannot be extrapolated from one optical regime and particle size to another and from one technique to another. For monodisperse suspensions the particle size can always be estimated using turbidimetry, provided that two turbidity measurements at widely separated wavelengths together with a measurement of the particle volume fraction in the suspension is used. This is irrespective of the optical properties of the suspension (refractive indices of particles and medium, wavelength of light) and the size of the particles. In some simpler cases only two turbidity measurements or measurement of one turbidity and the volume fraction are sufficient. For polydisperse suspensions, turbidity measurements at sufficient wavelengths (the number depends on the detail of the PSD one wishes to resolve) together with a measure of the particle volume fraction are required for the determination of the full PSD. However, for certain combinations of particle sizes and optical properties, the method cannot provide the full PSD, but only an average of the PSD. This limitation is simply a result of the light scattering patterns and it is expected theoretically. More specifically, it stems from the fact that for some combinations of optical properties and particle size, a light scattering function (the wavelength exponent) changes very slowly with the relative size of the particles to the wavelength. When this happens, in the presence of experimental noise, estimation of the full PSD is not possible. In some cases this limitation can be overcome by simply altering the optical properties of the suspension (i.e. choosing proper wavelengths for the turbidity measurements or a medium different than water to suspend the particles). Therefore, to make the best use of the method and interpret the results in a meaningful way, one should be aware of the regimes where this limitation occurs.

Because of the behavior of the wavelength exponent, turbidimetric techniques that utilize the measurement of the particle volume fraction (which is a measurement of

Table 1 Examples of applications of turbidimetry in particle sizing[a]

System	m	Particle size, D (μm)	Wavelengths (nm)	Turbidimetric method	Assumed PSD[b]	Comments[b]	Other methods[b]
Minerals[20]: TiO_2 $Al(OH)_3$ Al_2O_3 SiO_2	1.9 1.86 1.33 1.163	$0.1 < D < 10$	436, 546, 650, 800	Specific turbidity	Log-normal on weight basis	Estimated PSD agrees very well with measured PSD from centrifugal sedimentation	Centrifugal sedimentation
TiO_2 pigments.[25] Oval-shaped crystals. Estimate crystal size-area equivalent diameter	–	Mean crystal sizes: 0.086–0.237	190–1100	44 turbidities and volume fraction	No shape assumed. Estimate 26 heights of histogram in the range 0.012–0.6375 nm	Study involves empirical modeling with latent variables–PLS	TEM
Stable silver bromide sols in water[5]	1.7	$D < 0.25$	(1) 436, 546 (2) 450, 800	Specific turbidity	(1) Apparent diameters (2) Log-normal (ZOLD)	Important discussions on apparent diameters. See section 5	EM
Ostwald ripening process: silver bromide grains[6]	1.7	$D < 0.8$	2.22 μm	Specific turbidity	Apparent diameter (D_τ)	On-line monitoring of grain growth. See section 8	EM
Variety of materials[26] PVC, sand, protein, KCl	–	Weight average: 138 116, 196 20–30 92–284	900	Specific turbidity	Assumed γ PSD with known spread. Reported average size	Some particles too large. Only D_{32} expected to be correct.	Sieve Coulter counter
Polystyrene latexes[7]	1.2	$0.65 < D < 1.3$	440–610 basis: 546	Turbidity ratio	Positively skewed with maximum polydispersity 1.5	For polystyrene see also Haseler.[19] See sections 4.2 and 7.3	EM
Polystyrene[8]	1.2	Synthesized bimodal and trimodal PSDs	300–800	Turbidities only	No assumption on shape	Solve directly for the heights of the PSD	
Styrene–butadiene rubber and acrylonitrile–butadiene rubber[27]	1.16, 1.14	$0.04 < D < 0.14$	300–600 (101 points)	Specific turbidity	(1) Apparent D_τ (2) Log-normal (3) No shape assumption	Only D_τ correct	SEM DLS
Copolymer latexes: poly(butadiene–styrene)[28]	1.17, 1.15	$D < 0.4$	350–1000	Specific turbidity	Apparent diameters	See section 5.1	EM
Photographic dye-forming coupler dispersions[29]	1.166, 1.21	$0.05 < D < 1.0$	400–800	Specific turbidity and wavelength exponent	Log-normal on weight basis (verified by EM)	Conclude that success of method depends on values of α	EM

the particle size and number independent of the scattering properties) provide reliable estimates for the particle size (the PSD or an average diameter) in a wider range of sizes and optical properties than techniques that utilize turbidity measurements only.

In this article, a brief overview of light scattering theory is first presented followed by a description of the turbidimetric techniques that are most commonly used for particle size determination. For each technique we include its theoretical background, comments on its advantages and limitations and references to its successful applications in the literature. We also include discussions regarding the regions of particle sizes and optical properties where the technique may present difficulties in providing reliable estimates of the particle size or the PSD. We then present cases where turbidimetry was used to provide estimates of the average diameters of the PSD and discuss the advantages and pitfalls of such uses. We follow with details on the procedure such as choice of wavelengths, calculation of refractive index and instrumentation. The sensitivity of the turbidimetric methods to experimental error is extensively discussed. Applications on the use of the method for on-line particle size measurements follow. We conclude with a discussion on how users should proceed with choosing the appropriate method for their application and with comparing results from other particle sizing techniques. Throughout the article several applications reported in the literature are critically discussed in order to point out some approaches with serious limitations and some coincidental observations that may result in misleading conclusions. In this way the readers can judge if the approaches reported in the literature are suitable for their use.

2 THEORETICAL BACKGROUND

2.1 Turbidity and Particle Size

Turbidity, τ_{λ_0} (cm^{-1}), gives a measure of the attenuation of the intensity of a beam of light traversing through a suspension of particles (Equation 1):

$$\tau_{\lambda_0} = \frac{1}{l} \ln \left(\frac{I_0}{I} \right. \tag{1}$$

where I_0 and I represent intensities of the incident and transmitted beams, respectively, and l is the length of the optical path (i.e. cell length, cm). The value of the turbidity changes with the wavelength of the incident light beam, λ_0. I is measured at 180° to I_0.

The attenuation of the intensity of light traversing through a particle suspension is due to scattering of light by the particles and in some cases (depending on the wavelength) absorption of light by the particles and/or the medium. The amount of light scattered and absorbed by the particles depends on their size, their concentration in the suspension, the size of the particles relative to the wavelength of the incident beam and the refractive indices of the particles and the medium. Therefore, theoretically, turbidity can be related to the particle size. For a monodisperse suspension (particles of equal diameter, D) of spherical, isotropic particles, in the absence of multiple scattering (Equation 2):

$$\tau_{\lambda_0} = N \frac{\pi D^2}{4} K_{\text{ext}} \tag{2}$$

where N is the number of particles per cm^3 and K_{ext} is the extinction coefficient at wavelength λ_0. K_{ext} is equal to the sum of the absorption K_{abs} and the scattering K_{scat} coefficients. The extinction coefficient can be calculated from the rigorous Mie theory and the equations for this calculation can be found in several sources.[3,33–36] In the work presented in this article we assume no absorption ($K_{\text{ext}} \equiv K_{\text{scat}}$) and this is the case for most of the work reported in the literature. In most of the reported applications workers have chosen to avoid wavelengths where the medium or the particles absorb, for practical reasons, explained in section 6.3. However, should readers decide to work with absorbing particles, they should use K_{ext} for Equations (3), (4), (12), (13), (15) and (18). The validity of the discussions in this article does not change with the nonabsorption assumption.

For a monodisperse suspension of spherical, nonabsorbing, isotropic particles, in the absence of multiple scattering (Equation 3):

$$\tau_{\lambda_0} = N R_{\text{scat}} = N \frac{\pi D^2}{4} K_{\text{scat}} = N \frac{\pi D^2}{4} K \left(\frac{D}{\lambda_m}, \frac{n_p}{n_m} \right. \tag{3}$$

where R_{scat}, the scattering cross-section, is the total energy scattered by one sphere when the incident light is of unit intensity and either plane polarized or unpolarized. The scattering coefficient, K_{scat}, or $K(D/\lambda_m, n_p/n_m)$, is dimensionless and it is an involved function of two parameters, α and m. $\alpha = \pi(D/\lambda_m)$ is defined as the relative size of the particle diameter to the wavelength of the light in the medium (λ_m) and $m = n_p/n_m$ is the ratio of the refractive index of the particles to the refractive index of the medium. $\lambda_m = \lambda_0/n_m$, where λ_0 is the wavelength of the incident beam in vacuo. Both n_p and n_m are evaluated at λ_0. The estimation of the refractive indices for homogeneous and inhomogeneous particles is discussed in section 6.2. In cases where the particles absorb, the refractive index has both real and imaginary parts.

For a polydisperse suspension of spherical nonabsorbing, isotropic particles, in the absence of multiple

scattering turbidity is given by Equation (4):

$$\tau_{\lambda_0} = N \int_0^{\infty} \frac{\pi D^2}{4} K\left(\frac{D}{\lambda_m}, \frac{n_p}{n_m}\right) f(D)\, d(D) \qquad (4)$$

where $f(D)$ is the normalized PSD.

In general, because K_{scat} is an involved nonlinear function of α (i.e. D/λ_m), it is possible from turbidity measurements at a sufficient number of wavelengths (or a combination of turbidity measurements and other properties of the particle suspension) to estimate the size of the particles in a monodisperse suspension or the PSD in a polydisperse suspension. However, it has been shown[32] that for certain combinations of (m, α) values the estimation of the particle size or the PSD of the suspension may present difficulties with some turbidimetric techniques. Being aware of these (m, α) regimes will help the user choose the proper turbidimetric technique and proper wavelengths to work with in order to obtain the most reliable estimate of particle size of a suspension.

2.2 The Scattering Coefficient

Certain features in the behavior of the scattering coefficient are important in explaining the capability of turbidimetric techniques to provide the particle size or the PSD of a suspension. These features will be discussed here in some detail. The scattering coefficient is defined as the ratio of the scattering to the geometrical cross-section. The scattering coefficient exhibits an oscillatory dependence on α, with a series of successive minima and maxima (Figure 1). The first maximum occurs at lower α values the larger is the value of m; the numerical value of K_{scat} at the first maximum is larger the larger is m. At large values of α, m has virtually no effect on K_{scat}, in agreement with the theory of diffraction for objects very large compared with the wavelength used, and K_{scat} approaches the value of 2. Values of K_{scat} for various large α values are shown in Table 2. Note that for $m = 1.2$ and $200 < \alpha < 220$ the value of the oscillating K_{scat} can be found between 2.12 and 1.99, whereas for $2500 < \alpha < 2700$, K_{scat} oscillates between 2.016 and 2.006. When plotted against α, the scattering coefficient also exhibits secondary fluctuations (ripples) that become increasingly irregular for higher values of m. Another parameter which is often used in light scattering is $\rho = 2\alpha|m - 1|$; ρ is the phase shift suffered by a wave passing through the center of a sphere.[37] When K_{scat} is plotted against ρ, the ρ position of the extremes (minima and maxima) of the main oscillation is independent of the value of m.[33,34] Recall that this discussion is for spherical, isotropic spheres. Scattering for nonspherical particles is an area of active research[38] and publications are available.[39–41]

Figure 1 Scattering coefficient, K_{scat}, plotted against α for $m = 1.1$ and 1.2.

As mentioned earlier, in the general case the scattering coefficient can be calculated from the rigorous Mie theory.[3,33–36] In certain (m, α) regimes the equations for K_{scat} can be approximated with simple expressions which give K_{scat} within 1% accuracy from its true value.[37] These expressions are discussed here because they help in elucidating some of the problems encountered by researchers when converting turbidity measurements to particle size.

1. When the suspended particles are very small compared with the wavelength both outside ($\alpha \ll 1$) and inside ($|m\alpha| \ll 1$), the particle,[34,37,42] the Rayleigh scattering theory gives Equation (5):

$$K\left(\frac{D}{\lambda_m}, \frac{n_p}{n_m}\right) = \frac{8}{3}\left(\frac{m^2 - 1}{m^2 + 2}\right)^2 \alpha^4 \qquad (5)$$

2. For particles very large compared with the wavelength, the scattering coefficient approaches a

Table 2 Range of values (maximum–minimum) observed for the oscillating K_{scat} in different ranges of α values for $m = 1.1$ and 1.2

m	$20 < \alpha < 40$	$80 < \alpha < 100$	$140 < \alpha < 160$	$200 < \alpha < 220$	$800 < \alpha < 1000$	$1500 < \alpha < 1700$	$2500 < \alpha < 2700$
1.1	3.45–1.64	2.39–1.88	2.24–1.99	2.175–1.98	2.051–1.998	2.03–2.002	2.0195–2.002
1.2	2.7–1.7	2.26–1.94	2.16–1.98	2.12–1.99	2.0365–2.0065	2.023–2.006	2.016–2.006

constant value independent of m[3,33,34,37] (Equation 6):

$$K\left(\frac{D}{\lambda_m}, \frac{n_p}{n_m}\right) = 2 \quad (6)$$

Walstra[37] has reported that this is true for $\rho = 2\alpha|m-1| > 300$ and $\alpha > 2000$. Table 2 gives the range of K_{scat} values for different α values and $m = 1.1$ and 1.2. Note that for $m = 1.2$ and α values between 200 and 220 the values of the oscillating K_{scat} can be found between 2.12 and 1.99. Assuming a constant value of 2.0 may introduce a maximum of 6% error in K_{scat} in this range. For very large values of α, assuming $K_{scat} = 2.0$ gives K_{scat} within 1% accuracy from the true value.

Equations (5) and (6) are the two extremes of a general expression where for monodisperse suspensions of nonabsorbing spheres, the dependence of the scattering coefficient on the diameter at a given wavelength is approximated by Equation (7):[4,5]

$$K\left(\frac{D}{\lambda_m}, \frac{n_p}{n_m}\right) = k'\left(\frac{D}{\lambda_m}\right)^z = k'_c\alpha^z \quad (7)$$

where k' and k'_c are proportionality constants. Note that $z = 4$ in the Rayleigh regime and $z = 0$ for large particles (compare Equation 7 with Equations 5 and 6, respectively). When plotting K_{scat} against the wavelength for constant D, we have $K_{scat} = k''\lambda_0^{-z}$, and therefore z has been termed "the wavelength exponent".[43] When plotting K_{scat} against α at constant λ_m, we can write Equation (8):

$$\ln(K_{scat}) = z\ln a + \ln k'_c \quad (8)$$

The value of z can be obtained for any α at any m value from the slope of $\ln K_{scat}$ vs $\ln\alpha$.

2.3 Turbidity and Moments of the Particle Size Distribution

In regimes where K_{scat} can be approximated by Equation (7), the turbidity of a monodisperse suspension at a given wavelength λ_0 can be written as $\tau = NkD^y$, where $y = z + 2$ and k is a constant. Several authors[5,43] have tabulated values of y or z for several pairs of (m, α) values (in the notation of Heller et al.,[43] $z \equiv n$). Values of y and z are plotted in Figure 2 for several m values and $\alpha \leq 12.0$. From Equations (4) and (7), for a polydisperse system, at a given λ_0, we can write Equation (9):

$$\tau_{\lambda_0} = N\int_0^\infty k(D)D^{y(D)}f(D)\,d(D) \quad (9)$$

Figure 2 Exponents y and z for $m = 1.05, 1.1, 1.15, 1.2$ and 1.25.

where both k and y are functions of D. When the particle sizes in the suspension are such that k and y do not change significantly with D, then (Equation 10):

$$\tau_{\lambda_0} = Nk\int_0^\infty D^y f(D)\,d(D) = NkJ_y \quad (10)$$

where k and y are constants. In these cases, turbidity is proportional to the yth moment, J_y, of the PSD. The value of y (i.e. the order of the moment) changes with α and m (Figure 2). For $\alpha < 0.5$, y approaches the limiting value of 6 ($z = 4$, Rayleigh regime) and therefore turbidity is proportional to the sixth moment of the PSD. For values of m between 1.1 and 1.2, and for $\alpha < 1.6$, the value of y is almost independent of the value of m. Kourti et al.[15,32,44] discussed that for small values of m ($m = 1.05, 1.1, 1.15$) the value of y is approximately 4.0 ($4.2 \leq y \leq 3.8$) for a very wide range of α values (for $m = 1.05$, $3 < \alpha < 14$; for $m = 1.15$, $3 < \alpha < 6$). For suspensions with PSDs in the above (m, α) regions, turbidity would be approximately proportional to the fourth moment of the PSD. Finally, for very large particles, $y = 2$ and turbidity is proportional to the second moment of the PSD.

3 PARTICLE SIZE DETERMINATION IN MONODISPERSE SUSPENSIONS

The turbidity of a suspension of spherical particles as given in Equation (3) is a function of both the number concentration of particles (N) and the particle diameter (D). The estimation of these two unknowns requires sufficient measurements of turbidity at different wavelengths or measurements of turbidity and another property that is also related to particle concentration and diameter. Two approaches have been used in the literature:[33] the turbidity at a given wavelength is divided

either by the particle volume fraction or by the turbidity value at another wavelength, such that the unknown number of particles is eliminated, and the new quantity is related to particle size only. Once the particle size is determined, substitution into Equation (3) will give N.

3.1 Specific Turbidity

The volume fraction of the spherical particles in a monodisperse suspension is given by Equation (11):

$$\phi = N\frac{\pi D^3}{6} \tag{11}$$

The particle volume fraction can be measured (see section 6.5) using gravimetric analysis or densitometry.[21,23,45] The specific turbidity, defined as the ratio of the turbidity of the suspension to the volume fraction of the suspended particles, is independent of the particle number concentration (Equation 12):

$$\frac{\tau_{\lambda_0}}{\phi} = \frac{3}{2}\frac{K\ \ \frac{D}{\lambda_m}, \frac{n_p}{n_m}}{D} \tag{12}$$

Specific turbidity is plotted against diameter in Figure 3 for two different types of particles suspended in water: poly(vinyl acetate) with $m \approx 1.1$ and polystyrene with $m \approx 1.2$. The particle diameter D can be calculated from one turbidity measurement and the particle volume fraction when the optical properties of the suspension are known and the expected particle size range is known. For example, if it is known that we have submicrometer particles then one specific turbidity measurement for poly(vinyl acetate) at 600 or 400 nm would give the particle diameter. Note that owing to the oscillatory behavior of the specific turbidity, more diameters may correspond to one specific turbidity value. For example, for polystyrene a specific turbidity reading of 15 000 cm^{-1} at 400 nm in the range shown in Figure 3 corresponds to six different diameters (0.15, 1.7075, 1.855, 1.865, 1.9225 and 2.56 μm; four due to the main oscillating pattern of K_{scat} and two due to a secondary rippling effect). Therefore, if the size range is not a priori known, measurements at two (preferably widely spaced) wavelengths are required to extend the applicability of the method to a wide range of particle sizes.[15] Once the particle size has been estimated, the concentration of the particles in the suspension (N) can be calculated from Equation (3). Note that in the Rayleigh regime, where K_{scat} is given by Equation (5), the specific turbidity at given λ_m is directly proportional to the volume of the particles ($\tau/\phi \propto D^3$), and that for very large particles ($K_{scat} = 2.0$) it is proportional to the inverse of the diameter ($\tau/\phi = 3/D$).

Figure 3 Specific turbidity plotted against particle diameter for monodisperse poly(vinyl acetate) and polystyrene latexes at 400 and 600 nm.

3.2 Turbidity Ratio

The ratio of two turbidity readings taken at two wavelengths is a quantity independent of the particle number concentration (Equation 13):

$$\frac{\tau_{\lambda_{01}}}{\tau_{\lambda_{02}}} = \frac{K\ \ \frac{D}{\lambda_m}, \frac{n_p}{n_m}\ \ _{\lambda_{01}}}{K\ \ \frac{D}{\lambda_m}, \frac{n_p}{n_m}\ \ _{\lambda_{02}}} \tag{13}$$

Subscripts λ_{01} and λ_{02} denote that the quantities τ, n_p, n_m and λ_m are evaluated at these wavelengths; λ_{01}, λ_{02} are the wavelengths in vacuo. Figure 4(a) shows the turbidity ratio (at 400/600 nm) for polystyrene and poly(vinyl acetate) particles suspended in water. The particle diameter could be estimated from one turbidity ratio (two turbidity measurements) if the ratio was a monotonic function of particle size or α. However, this is not the case, as can be seen in Figure 4(a). An indentation exists in the turbidity ratio vs α curve, at the lower α regime, owing to the first inflection point of the K_{scat} vs α curve (in polydisperse suspensions, this indentation vanishes). Also, for larger particles, the turbidity ratio vs α curve exhibits an oscillatory behavior. Therefore, unless the size range is a priori known, a reading at a third wavelength (two turbidity ratios) is advised, to define uniquely the particle size. Again once the particle size is estimated the number of particles can be calculated from Equation (3).

An example where only one turbidity ratio is not sufficient to determine the particle size was reported by Kourti.[15] The turbidity ratio measurement at $\lambda_{01} = 400$ nm and $\lambda_{02} = 500$ nm for a 60 : 40 poly(styrene–butadiene) latex was repeated several times

Figure 4 (a) Turbidity ratio at 400/600 nm plotted against particle diameter for polystyrene with $m \approx 1.2$ and poly(vinyl acetate) with $m \approx 1.1$ latexes. (b) Turbidity ratios for polystyrene, $m \approx 1.2$. Note that owing to the oscillation in the curves, particle suspensions with two different diameters (0.2 and 0.25 μm) give the same turbidity ratio values at two different wavelengths.

(for four different dilutions of the same sample). Each time, two estimates (two solutions) of particle size were obtained. In one of the solutions the estimates of the diameter were between 209 and 228 nm and in the other between 157 and 165 nm. Results from other methods had shown that the true diameter range was around 200 nm [specific turbidity (208–221 nm), HDC (228 nm) and DLS (194 nm)] and therefore the first solution could be picked as the correct one.

Caution should be exercised when diameters are in a range around the first indentation in the turbidity ratio–diameter curve when using the turbidity ratio method. Figure 4(b) shows turbidity ratios (τ_{400}/τ_{600} and τ_{500}/τ_{600}) plotted against diameter for monodisperse polystyrene suspensions. The diameters are in a range around the first indentation in the turbidity ratio–diameter curve. Note that suspensions with two very different particle sizes (0.2 and 0.25 μm) will give the same turbidity ratio at two different wavelengths (1.72 for τ_{500}/τ_{600} and 3.54 for τ_{400}/τ_{600}). In fact, for this example, with an experimental error as small as 2.0% in the turbidity ratios, any solution between 0.2 and 0.25 μm is possible. It would be preferable if the three wavelengths at which the measurements were taken were more widely separated.

The turbidity ratio method practically gives no information on the particle size for (i) very large particles, where for all the wavelengths used the scattering coefficient is constant (substitution of $K_{scat} = 2$ in Equation 13 gives a turbidity ratio equal to unity), and (ii) very small particles, where for all the wavelengths used the Rayleigh Equation (5) applies and turbidity ratio becomes independent of the particle size.

4 PARTICLE SIZE DISTRIBUTION DETERMINATION IN POLYDISPERSE SUSPENSIONS

Specific turbidity and turbidity ratio measurements can also be used to estimate the PSD in polydisperse suspensions. Numerical approaches that can be used to solve for the PSD from turbidity and specific turbidity measurements are discussed in detail in section 4.5. However, the estimation of the full PSD is not always possible with turbidimetry.[15,32] Some turbidimetric techniques are not theoretically expected to provide the full PSD of a suspension if, because of its optical properties (refractive indices of medium and particles) and the sizes of the particles, the (m, α) values of the suspension are within certain ranges. In such cases the specific turbidity technique will provide an estimate of an average diameter while techniques similar to the turbidity ratio provide no information on the particle size. The (m, α) regimes where the estimation of the full PSD is practically possible are discussed for each one of the turbidimetric methods presented in this section.

4.1 Specific Turbidity

Examples of successful applications of the method for particle and droplet size distribution determination can be found in Meehan and Beattie,[5] Walstra[16] and Yang and Hogg.[20] For a polydisperse suspension of spherical particles, the volume fraction is (Equation 14):

$$\phi = N \int_0^\infty \frac{\pi D^3}{6} f(D)\, \mathrm{d}(D) = N \frac{\pi}{6} J_3 \qquad (14)$$

where J_3 is the third moment of the PSD. The specific turbidity is given by Equation (15a):

$$\frac{\tau_{\lambda_0}}{\phi} = \frac{3}{2} \frac{\int_0^\infty D^2 K\left(\frac{D}{\lambda_m}, \frac{n_p}{n_m}\right) f(D)\,\mathrm{d}(D)}{\int_0^\infty D^3 f(D)\,\mathrm{d}(D)} \quad (15a)$$

Alternatively, the specific turbidity of a suspension can be written as Equation (15b):

$$\frac{\tau_{\lambda_0}}{\phi} = \int_0^\infty \frac{\tau}{\phi}(D, \lambda_0) F(D)\,\mathrm{d}(D) \quad (15b)$$

where $\tau/\phi(D, \lambda_0)$ is the specific turbidity corresponding to particles with diameter D and wavelength λ_0 and $F(D)$ is the normalized PSD on a weight basis.

For a suspension of spheres, when the optical properties of the suspension are known, a minimum of P specific turbidity measurements are required for the estimation of a P parameter PSD from Equation (15a) or (15b), as discussed in the next section. For example, if we assume that the PSD is known to be log-normal described by the mean diameter and the variance, we need at least two specific turbidity measurements. If the form of the PSD is not assumed and we attempt to recover the frequency distribution at P given diameters (i.e. P discrete points), then at least P specific turbidity measurements are required.

In the presence of experimental error, the estimation of the full PSD from Equation (15a) or (15b) is impossible if all the turbidities (i.e. at all the wavelengths required for the estimation) are approximately proportional to the same moment of the PSD, J_y. Given that ϕ is always proportional to the third moment J_3 of the PSD, in these cases specific turbidity becomes proportional to J_y/J_3, that is proportional to the $(y-3)$rd power of the D_{y3} average diameter.[32] Kourti et al.[32] showed that when this happens for all of the P wavelengths used, many alternative solutions (PSDs) correspond to the same specific turbidity measurements and it is impossible to isolate the true solution unless there is some a priori knowledge. However, all these alternative solutions have their D_{y3} average diameters numerically very close to each other. In that case it was suggested that only this average diameter D_{y3} can be correctly estimated from specific turbidities[15,32] in this range of wavelengths. The (m, α) regimes where the full PSD is practically impossible to estimate for nonabsorbing particles are as follows:

1. For any m value and very small α (Rayleigh regime). If for all the wavelengths used for the turbidity measurements we are in the Rayleigh regime, then substitution of Equation (5) in Equation (15a) gives Equation (16):

$$\frac{\tau_{\lambda_0}}{\phi} = k_{\lambda_0} \frac{\int_0^\infty D^6 f(D)\,\mathrm{d}(D)}{\int_0^\infty D^3 f(D)\,\mathrm{d}(D)} = k_{\lambda_0} \frac{J_6}{J_3} = k_{\lambda_0} D_\tau^3 \quad (16)$$

where D_τ (or D_{63}) is the turbidity-average diameter and $k_{\lambda_0} = 4\pi^4 \lambda_m^{-4}[(m^2-1)/(m^2+2)]^2$ and the subscript λ_0 denotes that τ, λ_m and m are evaluated at λ_0. Llosent et al.[27] tried to estimate the full PSD in the Rayleigh regime using either an assumed shape of the PSD or using a regularization method (discussed later) to solve at discrete points for the PSD. Their results confirmed the suggestions of Kourti et al.[32] that only the turbidity-average diameter can be correctly estimated in these regimes.

2. For any m value and very large diameters (where $K_{scat} \approx 2$), we have Equation (17):

$$\frac{\tau_{\lambda_0}}{\phi} = 3 \frac{\int_0^\infty D^2 f(D)\,\mathrm{d}(D)}{\int_0^\infty D^3 f(D)\,\mathrm{d}(D)} = 3\frac{J_2}{J_3} = \frac{3}{D_{32}} \quad (17)$$

D_{32}, the volume–surface average, is also sometimes referred to as the Sauter mean diameter.

3. (m, α) regimes where the exponent y is close to 4.0. In an extensive study with theoretical analysis and experimental validation, Kourti et al.[15,32] showed that for suspensions with PSDs in (m, α) regimes where the exponent y is very close to 4.0 ($3.8 < y < 4.2$), specific turbidities result in apparent diameters numerically very close to the weight average (D_w or D_{43}) of the true PSD. The regions of (m, α) values where this happens can be read from a y vs α plot, such as that in Figure 2. From such a plot we can see that $y \approx 4$, for $m = 1.05$ at $3.0 < \alpha < 14$ and for $m = 1.15$ at $3.0 < \alpha < 6.0$. If the whole distribution covers α values in this regime for all the wavelengths used for the turbidity measurements, then within experimental error many alternative solutions are possible and only the weight-average of the distribution can be correctly estimated. This is true for any type of distribution (multimodal or unimodal continuous distribution, or simply the mixture of two populations). Table 3 gives an illustration of the effect of small measurement errors on the estimation of the PSD in these regimes, for $m = 1.1$. In case A, the true distribution is log-normal (see Equation 21) with $D_g = 175\,\mathrm{nm}$ and $\sigma = 0.2$ and weight-average diameter $D_w = 201\,\mathrm{nm}$. The turbidities for such a suspension were theoretically calculated at three

Table 3 Illustration of effect of small random measurement errors on the estimated PSD for $m = 1.1$[a]

Case	True PSD				Different random error for each test	Estimated PSD			
	D_g (nm)	σ	D_N (nm)	D_W (nm)		D_g (nm)	σ	D_N (nm)	D_W (nm)
A	175	0.2	178	201	A1	116	0.39	125	199
					A2	198	0.08	198	202
B	455	0.2	464	523	B1	520	0.002	520	520
					B2	336	0.362	359	533

[a] Two cases with different true PSDs are examined: (A) $D_g = 175$, $\sigma = 0.2$ and (B) $D_g = 455$, $\sigma = 0.2$. A maximum error of $\pm 1.2\%$ was introduced randomly in the specific turbidities at several wavelengths. Then the PSD was re-estimated. For each case two different random errors were tried, and two very different PSDs were obtained, both far from the true solution, but with D_w close to the true solution.

wavelengths. An error of less than 1.0% was then introduced in the three turbidity values and the parameters of the PSD were re-estimated (case A1). Note that the estimated $D_w = 199$ is within 1% of the value of the true weight average of the PSD whereas D_g and σ are significantly different. A different random error less than 1% was introduced in the three turbidities for case A2. Again, only the weight average of the estimated distribution $D_w = 202$ is within 0.5% of the true value and the other parameters are significantly different from the true distribution but also from case A1. Similar results were obtained for case B. For different random errors of $\pm 1.2\%$ on the turbidity values, cases B1 and B2 were obtained with weight averages within 2% of the true value but with all the other parameters significantly different from the true distribution.

Reports in the literature confirm that the PSD cannot be estimated with specific turbidity in some cases. Haseler[19] working with Ektacolor suspensions ($m = 1.15$) reported that experimental errors in specific turbidities (measured at 400 and 700 nm) would lead to large errors in the calculated distribution. These results were observed because of the small (m, α) values with which he was working. Based on the above discussion, only D_w could be correctly estimated in those (m, α) regimes. Walstra,[16] trying to estimate the globule size distribution in cow's milk ($m = 1.1$) from specific turbidity measurements, reported that for very fine emulsions ($D_{32} < 200$ nm) with rather high polydispersity the reliability of the method decreases and showed that a set of experimental data could be fitted to many different types of distributions with the same D_w.

The observations of Kourti et al.[15,32] revealed a very useful property of the specific turbidity: the weight-average diameter of suspensions can be correctly estimated even though the determination of the PSD is impossible. This property of specific turbidity can be utilized for practical purposes where a fast estimate of the weight-average diameter is required and is sufficient to monitor the progress of a process. Gossen[23,24,46] utilized this information and used specific turbidity to monitor the progress of polymerization reactions with on-line measurements. The α range where specific turbidity measurements give D_w may be extended further when the distribution is log-normal. For example, for suspensions with $m = 1.1$ and log-normal distributions of submicrometer particles, it has been observed that the mean value of the apparent diameters, estimated from specific turbidities at 400 and 600 nm, is within 5% the true weight average diameter of the PSD.[15,32] Monitoring these two apparent diameters gives information on the weight average of the PSD.

It should be noted that in all the regimes where the estimation of the full PSD is impossible, specific turbidity gives good estimates of meaningful average diameters. Compared with other turbidimetric techniques, where information only from turbidity measurements is used, the specific turbidity has the advantage that an additional measurement is used, the solids volume fraction, which is always proportional to the third moment of the PSD. Therefore, whenever turbidities at two or more wavelengths are proportional to the yth moment of the distribution, although the estimation of the true PSD is impossible, a meaningful average of the PSD, the D_{y3} average, can always be obtained from specific turbidity measurements.

4.2 Turbidity Ratio

The ratio of two turbidity readings taken at different wavelengths for a polydisperse suspension is given by Equation (18):

$$\frac{\tau_{\lambda_{01}}}{\tau_{\lambda_{02}}} = \frac{\int_0^\infty D^2 K\left(\frac{D}{\lambda_m}, \frac{n_p}{n_m}\right)_{\lambda_{01}} f(D)\,\mathrm{d}(D)}{\int_0^\infty D^2 K\left(\frac{D}{\lambda_m}, \frac{n_p}{n_m}\right)_{\lambda_{02}} f(D)\,\mathrm{d}(D)} \tag{18}$$

Again, subscripts λ_{01} and λ_{02} denote that the quantities τ, n_p, n_m and λ_m are evaluated at the corresponding wavelengths; λ_{01}, λ_{02} are wavelengths in vacuo. For a PSD described by P parameters, a minimum of $(P + 1)$ turbidity measurements at different wavelengths (one of

which is chosen as reference) are required, in principle, for the estimation of these parameters. The method gives no information on the particle size in the following cases, for nonabsorbing particles:

1. For any value of m and very large particles where $K_{scat} = 2$, the turbidity ratio equals 1.0.
2. For any value of m and very small particles, where the Rayleigh Equation (5) applies, the turbidity ratio equals a constant value, independent of the particle size.
3. When, for all the wavelengths used, turbidities are approximately proportional to the same moment of the PSD. This case is observed for very small m values ($m \approx 1.15, 1.1, 1.05$) and for a very wide range of α values below the first K_{scat} maximum, where the exponent y changes very slowly with α. This in turn means that even for broad distributions with sizes falling in these α regimes, turbidities at widely separated wavelengths will be proportional to approximately the same moment of the PSD, and their ratio will be almost independent of the particle size. Kourti et al.[15,32] showed that for $m = 1.1$ and submicrometer particles, the estimation of the true PSD from turbidity measurements at 350 and 700 nm (with reference $\lambda_0 = 546$ nm) is impossible for measurement errors as small as 0.5%. One example is reported in which the effect of error on the estimated PSD is studied for a turbidity ratio error as small as $\pm 0.35\%$ in the above three wavelengths. The PSD was re-estimated for different errors (less than $\pm 0.35\%$) each time. Several very different log-normal distributions were obtained; for example, one of the estimated PSDs had a geometric mean $D_g = 500$ nm and standard deviation $\sigma = 0.15$, $D_w = 541$ nm and polydispersity 1.05, while another had $D_g = 285$ nm, $\sigma = 0.4$, $D_w = 499$ nm and polydispersity 1.6.

The turbidity ratio method should therefore be avoided for the estimation of the PSD for systems of very small or very large particles and for systems with small m values ($m < 1.15$) and α values below approximately 10 (for a short wavelength of 400 nm and water medium, these α values cover all the submicrometer size range). In these regimes the method is so sensitive to experimental error that it offers practically no information on the size of the suspended particles (i.e. neither the PSD nor an average can be estimated).

Owing to the behavior of the turbidity ratio in the ranges of (m, α) values described above, controversial reports on the capabilities of the turbidity ratio to provide the full PSD have appeared in the literature. Wallach and Heller[7] obtained estimates very close to the true distribution for polystyrene suspensions ($m = 1.2$) with particle diameters between 650 nm and 1.3 μm from turbidity measurements at $\lambda_{01} = 440$ nm, $\lambda_{02} = 610$ nm and $\lambda_{03} = 546$ nm. The values of m and α in their system were such as to allow for successful PSD determination. However, when Haseler[19] tried the turbidity ratio method for a system with smaller m and α values ($m = 1.15$, λ_0 in the range 400–700 nm and submicrometer particles), he reported that within experimental error a large number of different distributions gave the same turbidity spectra. Similarly, Maxim et al.[31] reported that the "turbidity ratio leads to multivalued solutions and unless prior estimates of the answer by some other method are available there are no criteria for choosing between alternative solutions". They were working with small m values ($m = 1.1$), submicrometer particles and wavelengths of 320–720 nm with a reference wavelength of 546 nm, that is an (m, α) area where Kourti[15] showed that even a 0.5% error in the turbidity ratio measurements means that the PSD estimation is practically impossible. The results of both Haseler and Maxim et al. were expected based on the (m, α) values of their systems. It is clear from the above examples that one cannot generalize conclusions on the capability of turbidimetric techniques to provide the PSD across (m, α) values.

4.2.1 Methods Similar to Turbidity Ratio

Alternatively to Equation (18), some authors[47,48] use the ratio given in Equation (19):

$$\frac{(\tau\lambda/\phi)_{\lambda_{01}}}{(\tau\lambda/\phi)_{\lambda_{02}}} \tag{19}$$

Notice that, numerically, ϕ is eliminated from Equation (19), hence there is no reason to measure it. Other authors use the DQ (dispersion-quotient) method (Equation 20):[33]

$$DQ = \frac{\tau_{\lambda_{01}}\lambda_{02}^2}{\tau_{\lambda_{02}}\lambda_{01}^2} \tag{20}$$

Both of the above approaches have the same limitations as the turbidity ratio method for the estimation of the PSD.

4.3 The Wavelength Exponent Technique

In this approach, the particle size can be estimated only from turbidity measurements as in the turbidity ratio technique (i.e. the particle volume fraction does not need to be known). The change of the turbidity of a suspension with the wavelength is recorded and related to the size of the suspended particles. The technique is described in detail in Bateman et al.,[49] Heller et al.[43] and Kourti.[15] It has been shown[15,50] that the turbidity ratio and the wavelength exponent are theoretically equivalent

methods for the determination of the parameters of the PSD. The functions used in the formulations of the two techniques to convert the turbidity measurements to PSDs can be derived from each other, and in case of no measurement error the use of either method gives identical results. Consequently, in the (m, α) regions where the estimation of the particle size in a suspension is not possible using the turbidity ratio method, the wavelength exponent method also fails. It should also be noted that although the two methods are theoretically equivalent for the determination of the PSD, the formulation of the turbidity ratio method is less complex than that of the wavelength exponent. Consequently, the turbidity ratio method requires less computation to calculate the PSD and the error propagation is smaller.

Melik and Fogler[48] suggested an approach in which a combination of the wavelength exponent and the turbidity ratio method is used and claimed that with this approach the two parameters of the PSD can be estimated from only two turbidity measurements. However, since these are not two different methods but are theoretically equivalent, at least three turbidity measurements are required for the determination of a two-parameter PSD using either of the methods or their combination. Otherwise (i.e. using two turbidity measurements only), an infinite number of solutions will be obtained. The claims of Melik and Fogler[48] were shown[50] to be unfounded.

4.4 Resolution of a Conflict in the Literature

The analysis presented by Kourti et al.[15,32] which showed that the capability of a turbidimetric technique to provide the PSD is strongly related to the (m, α) values of the suspension helped to resolve a controversy that existed in the literature. This conflict, on whether the true PSD of a suspension can be estimated from turbidimetric techniques, arose between Maxim et al.[31] and Zollars.[11,12] As discussed earlier, Maxim et al. used the turbidity ratio method to estimate the full PSD in commercial suspensions, with $m = 1.1$ and particles with diameters smaller than 1.0 μm. A high correlation between the parameters of the distribution was observed. The authors stated that a valid estimate of the true distribution is impossible in the presence of experimental error. According to the analysis presented by Kourti et al.[32] these observations are justified (and were expected) for the (m, α) values of the suspension and the turbidity ratio method. Zollars used a simulation study with no experimental error to re-estimate the parameters of log-normal PSDs from theoretically calculated specific turbidities. Of course, the parameters were correctly re-estimated. The author stated that ''turbidimetry does not exhibit multiple solutions as reported by other investigators''. His observations[11,12] are also justified for a specific turbidity method and re-estimation of the parameters with no experimental error. Both the workers were correct for the types of cases they were studying. However, their findings cannot be extrapolated over turbidimetric methods and (m, α) regimes. This extrapolation caused the controversy.

4.5 Solving for the Particle Size Distribution

Equations (15a) and (18) give the value of the specific turbidity or turbidity ratio, respectively, at given wavelengths if the PSD, $f(D)$, is known. The inverse problem is to determine the PSD given the turbidity or the specific turbidity measurements at several wavelengths, λ_{0i}. If a continuous set of measurements of τ_{λ_0} vs λ_0 was available, one could theoretically deconvolute these equations to yield $f(D)$. However, in practice, one usually has turbidity measurements at a finite number of wavelengths, so we have to reconstruct $f(D)$ from only a number of discrete values of $\tau_{\lambda_{0i}}$. This is a typical problem in science.[51] We routinely measure ''enough points'' and then ''draw a curve through them''. In doing so for this problem, we are making some assumptions either about the underlying function $f(D)$ or about the nature of K_{scat}, or both.

Two approaches have been taken in the literature to solve for $f(D)$. When a small number of turbidity measurements are available, a type of distribution that can be described by a few parameters is assumed for $f(D)$ (i.e. Gaussian, log-normal, etc.) and we solve for these parameters. When many turbidity measurements are available it is possible in some cases to solve for f_j [the discretized $f(D)$] at a number of selected diameters, D_j. In general, the second approach requires many more turbidity measurements than the first.

4.5.1 Approximate the Particle Size Distribution with a Known Distributional Form

When a small number of turbidity measurements are available, a convenient approach is to approximate $f(D)$ with a distributional form that can be described by a few parameters. This form is then substituted into Equation (15a) or (18) and its parameters are estimated from the turbidity measurements using non-linear parameter estimation procedures such as the Levenberg–Marquardt algorithm.[52] The assumed distributional form is one that is known to describe similar systems (e.g. for latex particles the log-normal distribution described by two parameters is frequently used).

Extensive reviews on the distributional forms that have been used to describe the PSD in various suspensions can be found in several sources.[15,33,53] Some workers[1] calculated turbidity for a Gaussian distribution of spheres. However, most naturally occurring

populations are skewed and not symmetrical. The logarithmic normal distribution[11,15,20,33] has been used to described such populations. In this distribution $\ln D$ is normally distributed. The normalized PSD, $f(D)$ is given by Equation (21):

$$f(D) = \frac{1}{\sigma D\sqrt{2\pi}} \exp\ -\frac{(\ln D - \ln D_g)^2}{2\sigma^2} \qquad (21)$$

where $\ln D_g$ is the mean of $\ln D$ and D_g is both the median and the geometric mean diameter; σ is the standard deviation of $\ln D$ and it is called the geometric mean standard deviation. For small values of σ ($\sigma < 0.14$) the frequency curve can be closely approximated by a normal distribution.[33] The nth moment of the log-normal distribution is given by Equation (22):[54]

$$J_n = E(D^n) = \exp\ n(\ln D_g) + \frac{(n\sigma)^2}{2} \qquad (22)$$

The number- (D_N), volume–surface- (D_{32}), weight- (D_w) and turbidity- (D_τ) average diameters can therefore be calculated as (Equation 23):[15]

$$D_N = \frac{J_1}{J_0}; \quad D_{32} = \frac{J_3}{J_2}; \quad D_w = \frac{J_4}{J_3}; \quad D_\tau = \left(\frac{J_6}{J_3}\right.^{1/3} \qquad (23)$$

The calculation of the moments of the estimated PSD from Equation (22) are correct only if the integration is done from $D_{min} = 0$ to $D_{max} = \infty$ or, in practice, if the upper limit of the PSD, D'_{max}, is such that when using $f(D)$ from Equation (21), we have Equation (24):

$$\int_0^{D'_{max}} f(D)\,\mathrm{d}(D) = 1.0 \qquad (24)$$

Sometimes it may be known a priori (either from another method such as EM, DLS or particle chromatography, or by filtering of the suspension) that particle sizes smaller than D_{min} and/or larger than D_{max} do not exist. In these cases if we wish to estimate a log-normal envelope we can do so. In the parameter estimation all the integrations should be done between D_{min} and D_{max}. A log-normal envelope, characterized by D_g and σ, can be estimated; however, the PSD should be normalized before each iteration in the parameter estimation. Furthermore, the calculation of the various moments should be done using the explicit equation for the moments (Equation 25):

$$J_n = \int_{D_{min}}^{D_{max}} D^n f(D)\,\mathrm{d}D \qquad (25)$$

and not Equation (22). The log-normal distribution estimated with previous knowledge of D_{min} and D_{max} is expected to be a more accurate estimate of the true PSD, since the contribution of tails of very large particles to the theoretically calculated specific turbidity is eliminated.

Note that if Equation (22) can be directly used, then the polydispersity of a suspension with a log-normal distribution is given by $D_w/D_N = \exp(3\sigma^2)$ and the particle volume fraction is given by Equation (26):

$$\phi = ND_g^3 \exp(4.5\sigma^2) \qquad (26)$$

Some workers[4,5] had named as log-normal the distribution with the frequency function in Equation (27):

$$f'(D) = Df(D) \qquad (27)$$

The two distribution functions are related by Equation (28):[55–57]

$$f(D)\,\mathrm{d}D = f'(D)\,\mathrm{d}\ln D \qquad (28)$$

Therefore, if $f'(D)$ is used, then Equation (4) should be integrated with respect to $\ln D$[29] and not with respect to D. This distribution described by $f'(D)$, has been called a ZOLD.

When applying Equation (15b), $f(D)$ should be expressed on a weight basis. A log-normal distribution on a weight basis can be used.[20,29,58] If the number distribution is log-normal, then the weight distribution is also log-normal with the same geometric standard deviation σ (Equation 29):[54,59]

$$F(D) = \frac{1}{\sigma D\sqrt{2\pi}} \exp\ -\frac{(\ln D - \ln D_{wm})^2}{2\sigma^2} \qquad (29)$$

where $F(D)$ is the corresponding weight distribution for $f(D)$ of Equation (21). D_{wm} is both the median and the geometric mean diameter on a weight basis. D_{wm} and D_g are related by Equation (30):

$$D_{wm} = D_g \exp(3\sigma^2) \qquad (30)$$

Heller et al.[7,47,53] used another type of distribution that can be described by two parameters. However, the maximum polydispersity for that distribution is $D_W/D_N = 1.5$.[15] Therefore, even though the distributional form can describe positively skewed distributions, it cannot successfully describe highly polydisperse systems.

4.5.2 No Assumptions on Shape of Particle Size Distribution

If no distributional form is assumed for $f(D)$, then an alternative is to solve for $f(D)$ at a finite number of points.[8,60–64] In this approach, in the space of diameters from D_{min} to D_{max} we define P points (i.e. P diameters D_j, $j = 1:P$) and we try to estimate f_j at the corresponding diameter D_j. The number of P points must be less than

or equal to the number of specific turbidity or turbidity ratio measurements made.

Note that if the integrand of Equation (4) is discretized at $P-1$ intervals, then turbidity at a given wavelength λ_{0i} can be approximated by Equation (31):

$$\tau_{\lambda_{0i}} \approx \sum_{j=1=D_{\min}}^{j=P=D_{\max}} f_j \gamma_{ij} \tag{31}$$

where $f_j \approx Nf(D_j) = N_j$ is the discretized PSD and γ_{ij} depend on the kernel and the quadrature equation used.[27,61] γ_{ij} is evaluated at given D_j from the Mie theory. Note that for the simple case that the suspension is a mixture of P monodisperse suspensions with diameters $D_1, D_2, \ldots, D_P$, with relative number of particles $N_1, N_2 \ldots, N_P$, we have Equations (32) and (33):

$$\gamma_{ij} = \frac{\pi}{4} D_j^2 K(\lambda_{0i}, D_j) \tag{32}$$

$$\sum_{j=1}^{P} N_j = N \tag{33}$$

When turbidity is calculated for L wavelengths then Equation (31) can be written as Equation (34):

$$\boldsymbol{\tau} \approx \boldsymbol{\Gamma f} \tag{34}$$

where $\boldsymbol{\tau} = [\tau_{\lambda_{01}}, \tau_{\lambda_{02}}, \ldots, \tau_{\lambda_{0L}}]^{\mathrm{T}}$, $\boldsymbol{\Gamma} = \{\gamma_{ij}\}$, $\boldsymbol{f} = [f_1, f_2, \ldots, f_P]^{\mathrm{T}}$ and T denotes transpose.

In the inverse problem, we have to estimate $\boldsymbol{f}$ from turbidity measurements $\boldsymbol{\tau}^*$ (Equation 35):

$$\boldsymbol{\tau}^* = \boldsymbol{\Gamma f} + \boldsymbol{\varepsilon} \tag{35}$$

where $\boldsymbol{\varepsilon}$ is the vector of errors (measurement errors plus errors due to discretization of the true distribution). Solving Equation (35) is a linear algebra problem.[65] The least-squares solution is Equation (36):

$$\boldsymbol{f}_{\mathrm{ls}} = (\boldsymbol{\Gamma}^{\mathrm{T}}\boldsymbol{\Gamma})^{-1}\boldsymbol{\Gamma}^{\mathrm{T}}\boldsymbol{\tau}^* \tag{36}$$

However, because the rank of $\boldsymbol{\Gamma}$ is incomplete, small errors in $\boldsymbol{\tau}^*$ result in large errors in the estimated parameters. For this reason, regularization methods[65] should be used. A penalty function is introduced to the original least-squares problem (Equation 37):

$$\min_{\hat{f}} \{|\boldsymbol{\Gamma}\hat{\boldsymbol{f}} - \boldsymbol{\tau}^*|^2 + \xi q(\hat{\boldsymbol{f}})\} \tag{37}$$

where ξ is a nonnegative parameter and $|\ |$ indicates the modulus. $q(\hat{\boldsymbol{f}})$ could be the sum of squares, or the first or second differences, of the estimates. Eliçabe and Garcia-Rubio[61,62] added another term to the sum of squares of the second differences in order to force f_1 and f_{p} to zero (Equation 38):

$$q(\hat{f}) = \beta^2(\hat{f}_1^2 + \hat{f}_2^2) + \sum_{j=2}^{P-1}(2\hat{f}_j - \hat{f}_{j-1} - \hat{f}_{j+1})^2 \tag{38}$$

with $\beta \gg 1$. The solution now is:

$$\boldsymbol{f} = (\boldsymbol{\Gamma}^{\mathrm{T}}\boldsymbol{\Gamma} + \xi\boldsymbol{H})^{-1}\boldsymbol{\Gamma}^{\mathrm{T}}\boldsymbol{\tau}^* \tag{39}$$

where (Equation 40):

$$\boldsymbol{H} = \begin{matrix} 1+\beta^2 & -2 & 1 & 0 & 0 & 0 & \ldots & 0 \\ -2 & 5 & -4 & 1 & 0 & 0 & \ldots & 0 \\ 1 & -4 & 6 & -4 & 1 & 0 & \ldots & 0 \\ 0 & 1 & -4 & 6 & -4 & 1 & \ldots & 0 \\ \ldots & \ldots & \ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & 0 & 0 & 1 & -4 & 5 & -2 \\ 0 & 0 & 0 & 0 & 0 & 1 & -2 & 1+\beta^2 \end{matrix} \tag{40}$$

Note that in this method one has to choose the location of $D_{\min}$ and $D_{\max}$ and the number of intervals but also the value of ξ. The choice of these parameters was discussed in detail by Eliçabe and Garcia-Rubio.[61,62]

This technique was tested with simulations[61,62] for the estimation of unimodal and bimodal PSDs of varying breadth and mean diameter. Satisfactory results were reported[61] for broad distributions with particle diameters in the micrometer range (distributions with $D_{\max} = 1.45$ or $2.25\,\mu\mathrm{m}$). For $m = 1.2$ the results were not satisfactory for distributions covering sizes from 50 to 325 nm, that is, a regime where a large number of latex particle diameters are expected to be found.

More attempts to resolve the PSD with no assumptions were reported later by other workers.[63,64] Finally, an empirical method that relates turbidity measurements to particle size using latent variable methods has also been reported.[25]

Gulari et al.[8,60] tried to estimate PSDs in polystyrene suspensions ($m \approx 1.2$), from a large number of turbidity measurements at the wavelength range between 300 and 800 nm. In each case, the unknown PSD was assumed to be the sum of 20 equally spaced delta functions (γ_{ij} from Equation 32). The height (mass fraction) and position of each diameter was optimized using a nonlinear least-squares minimization procedure. During the analysis, the insignificant parameters are zeroed and the parameter matrix collapses until convergence is reached. The suspensions tested in that study were synthesized by mixing two or three monodisperse latexes, with particle diameters approximately 1 μm separated from each other. The distributions were resolved on a weight basis. In each distribution the weight fraction of the small particles was significant. Users should be careful when using this approach (i) when a very small weight fraction of the small particles is present (see discussion on bimodal

distributions, section 7.3) and (ii) for suspensions with (m, α) values where y does not change significantly with α. Readers should also keep in mind that the resolution of the method depends on the location of the assumed delta functions (number and width of ΔD intervals) and of course on the number of measurements (observations) available.

In general, the estimation of $f(D)$ at a finite number of points is expected to give satisfactory results only for certain suspensions (i.e. corresponding to certain m and α values). The results will be questionable in (m, α) regimes where y does not change significantly with α. Kourti and MacGregor[44] emphasized that more sophisticated deconvolution methods cannot overcome the limitations that turbidity ratio and specific turbidity have for particles in the (m, α) regimes where turbidity is simply proportional to a moment of the PSD. Several years later, Llosent et al.[27] confirmed this by trying several deconvolution approaches to estimate the PSD in the Rayleigh regime; only turbidity-average diameters could be correctly estimated and not the PSD.

4.5.3 The Method of Moments

This method was presented[9,10] as an alternative technique to solving for the PSD, but has some limitations for the particular application it was used. In this approach the term $K(D/\lambda_m, n_p/n_m)\pi D^2/4$ in Equation (4) is approximated with a polynomial (Equation 41):

$$K\left(\frac{D}{\lambda_m}, \frac{n_p}{n_m}\right)\frac{\pi D^2}{4} \approx \sum_{i=0}^{P} C_{i\lambda} D^i \tag{41}$$

Turbidity can thus be expressed as a sum of P moments of the unknown PSD. Using P turbidity ratios ($P+1$ turbidity measurements) one can estimate the P moments (J_0 of the normalized distribution is unity). The PSD is then represented analytically using a set of its moments, by modifying a gamma distribution which serves as a basis. The method was applied for particle size determination in poly(vinyl acetate) latexes.[9,10] First, the $C_{i\lambda}$ coefficients at each wavelength were estimated from Equation (41) by calculating the value of $K_{scat}\,\pi D^2/4$ exactly from the Mie theory for a set of 20 diameters (between 0.04 and 0.8 μm) and setting the value of P equal to 6. Six $C_{i\lambda}$ were estimated for each wavelength. The procedure was repeated for seven wavelengths (350–800 nm).

As discussed in a critical review,[15] the expansion of the scattering coefficient to a power series of α (or for constant λ_m, to a power series of D) is an approximation applicable for small α and $m\alpha$ values. In these cases the coefficients of α^i (or D^i) are known functions of the optical constants[37] (i.e. no estimation of $C_{i\lambda}$ is necessary). The α values corresponding to the diameters and wavelengths reported in the particular application[9,10] were very large (α as large as 9.5). For larger m and α values the approximating equations for the calculation of K_{scat} include more involved functions[37] of α [or $\rho = 2\alpha(m-1)$] than the simple power series expansion attempted in the method of moments. As discussed earlier, the term $K_{scat}\,D^2$ can be set proportional to D^y for larger values of α, and the value of y changes as a function of the particle size. For poly(vinyl acetate) latexes in particular, and for a very wide range of α values, the value of y is very close to 4.0. For most of the diameters used for the calculation of the above term in that study[9,10] at each wavelength, the α values were such that y was close to 4.0. It is clear that a reasonable value from the parameter estimation is expected only for $C_{4\lambda}$, since all the other coefficients are practically equal to zero. From the results reported by Kiparissides,[9] only $C_{4\lambda}$ seems to have a consistent value for all the wavelengths; the estimated values of all the other coefficients change, both in sign and value, randomly.[15] It should be clear that with meaningless estimates of the $C_{i\lambda}$ coefficients the correct estimation of the moments of the PSD is impossible.

5 ESTIMATION OF AVERAGE DIAMETERS

Several workers have tried to use turbidimetry to estimate only an average of the PSD of a polydisperse system. To do this they treat the system as monodisperse. That is, for specific turbidity, instead of using Equation (15a) they use Equation (12) and estimate a single, average diameter which is termed an ''apparent diameter'' (Equation 42):

$$\frac{\tau_{\lambda_0}}{\phi} = \frac{3}{2}\frac{K(\alpha_{av}, m)}{D_{av}} \tag{42}$$

where $\alpha_{av} = \pi D_{av}/\lambda_m$. D_{av} is the apparent diameter that always corresponds to the D_{y3} average of the PSD.

The concept of the ''apparent'' diameter was introduced and theoretically explained in very careful work by Meehan and Beattie.[4,5] They commented that the apparent diameter obtained by treating a polydisperse system as monodisperse corresponds to an average of the unknown PSD. They also concluded that different kinds of averages are yielded by different light scattering methods, and that the kind of average obtained by a light scattering method depends on the value of m of the suspension, the type of the PSD and the actual size of the particles in the suspension. Their comments have been corroborated by numerous reports[3,4,7,15,16,29,66] where it is either discussed and/or shown experimentally that the type of average obtained from the apparent diameter depends on the turbidimetric technique used and the m and α values of the suspension.

It has been suggested[7] that the ratio of the apparent diameters estimated at two wavelengths can provide a rough idea of the polydispersity of the system. However, this is not always true. It has already been shown that, sometimes, especially for small m values ($m \approx 1.1$), the apparent diameters corresponding to very broad distributions or to bimodal distributions do not change significantly with the wavelength, leaving the impression that the system is monodisperse. Note that for monodisperse systems, the apparent diameters obtained from two different turbidimetric methods (i.e. specific turbidity, turbidity ratio) should be numerically very close to each other (i.e. equal, within experimental error).

Specific turbidity has been the only turbidimetric method used in the literature for the determination of averages of the PSD. This is because, as already discussed, it is the only turbidimetric method that can provide estimates of meaningful averages of the PSD (D_{y3} averages) at some well-defined (m, α) regimes. The following averages may be obtained from specific turbidity: (i) the turbidity-average for very small particles ($\alpha < 0.5$) and any value of m, (ii) the volume–surface average for very large particles and any m value and (iii) weight-average for a combination of (m, α) values and $m < 1.2$ which can be identified very easily for the system under investigation. In this section we discuss the use of specific turbidity for the estimation of meaningful average diameters. A critical discussion of several applications reported in the literature is presented, so that the readers can identify with situations closer to their needs.

5.1 Turbidity-average Diameters

These averages can be obtained from specific turbidity measurements, for suspensions with any value of m, provided that all the particles in the suspension are small compared with the wavelength at which the turbidity measurements are taken (Rayleigh regime).

A practical application, where the growth of silver bromide grains is monitored on-line by following turbidity-average diameters, was reported by Haseler and Parkin[6] for an Ostwald ripening process. They were careful to choose long wavelengths [infrared (IR) regime, 2.22 μm] so that the Rayleigh scattering theory could be applied even for the largest particles in their system.[15]

Note that in the Rayleigh regime, if two particle suspensions have the same value of m, the ratio of their specific turbidities measured at the same wavelength (see Equation 16) gives the ratio of their turbidity-average diameters, independent of the value of m (Equation 43):

$$\frac{\tau_1/\phi_1}{\tau_2/\phi_2} = \left(\frac{D_{\tau_1}}{D_{\tau_2}}\right)^3 \qquad (43)$$

This characteristic can be exploited to provide a fast and inexpensive tool to monitor particle growth in a suspension where the value of m is not accurately known. By simply measuring specific turbidity (turbidity and solids fraction) at each time interval, the relative increase in the turbidity-average diameter as a function of time can be recorded. From a measurement of the diameter or the PSD with another technique (which is independent of m) at the end of the process, we can back-calculate the turbidity-average diameter at each instant in time.

A report[28] that a correct turbidity-average can be obtained for α values as large as 4.74 from specific turbidity measurements should be treated with caution. These observations were rather coincidental with the polydispersities of the systems investigated, as explained in detail elsewhere.[15] In the same work[28] the term ''weight'' average was used for what in fact is the ''turbidity'' average, as can be deduced from the definition in the original publication,[67] where EM results for the latex samples used in the later study[28] were presented.

5.2 Volume–Surface-average Diameters

Volume–surface-average diameters have been estimated in the literature from specific turbidity measurements of suspended particles that were very large compared with the wavelength ($K_{scat} \approx 2$). It should be noted that, although the value of the oscillating K_{scat} stays very close to 2.0 for large α values, the error by assuming it to be equal to 2.0 is small only for very large α values (i.e. the error is within 3% for $\alpha > 800$ and within 1% for $\alpha > 2000$) (see Table 2). For α values around 200–260, where some of the cases reported in the literature are, the error of assuming $K_{scat} = 2.0$, depending on the spread of the distribution, could be as large as 6% for $m = 1.2$ and 9% for $m = 1.1$ (at these α values K_{scat} still depends on m). Therefore, depending on the range of α values covered by the true distribution, the estimated D_{32} average diameter could be within 10% error of the true value.

Bagchi and Vold[66] showed experimentally that for very large particles, the specific turbidity varied linearly with the inverse of the volume–surface-average diameter ($1/D_{32}$). However, a linearity observed with respect to the inverse of other averages was coincidental and attributed to the fact that the degrees of polydispersity of the latexes investigated were very similar.[15] Kubota et al.[68] discussed this coincidental linearity and presented more experimental results from suspensions of various polydispersities, verifying that only the specific turbidity vs $(1/D_{32})$ curves are linear, as was theoretically expected.

Kourti[15] showed that a claim by Dobbins[69] and Dobbins and Jizmagian[70] that the volume–surface-average diameter can be obtained from one specific turbidity measurement in any particle size regime cannot

be supported. Their observations, that ''the specific turbidity is primarily dependent on the D_{32} diameter and only weakly dependent on the type of the distribution'', were shown to be coincidental with the types of distributions that they used for their investigation. These distributions had also their weight averages close to each other and all of them included particle sizes in the same range. Similar claims by Haseler[19] were also discussed in Kourti.[15] It was shown that in the examples reported by Haseler,[19] the estimated D_{32} was close to the true value because the location of the whole distribution was correctly estimated, and not because specific turbidity is always expected to give a correct D_{32} as claimed.[69,70]

It has been suggested[71] that the specific turbidity of a polydisperse system can be expressed as Equation (44):

$$\frac{\tau_{\lambda_0}}{\phi} = \frac{3}{2}\frac{K(\alpha_{\mathrm{av}}, m)}{D_{32}} \tag{44}$$

where (Equation 45):

$$K(\alpha_{\mathrm{av}}, m)\int_0^\infty D^2 f(D)\,\mathrm{d}(D) = \int_0^\infty D^2 K(\alpha_{\mathrm{av}}, m) f(D)\,\mathrm{d}(D) \tag{45}$$

where α_{av} corresponds to an average diameter D_{av}. It was suggested that the two parameters α_{av} and D_{32} can be used to interpret turbidity data over a wavelength range. The D_{32} diameter will correspond to the true PSD whereas α_{av} will correspond to the average diameter ''seen'' by the measurements ''averaged over the wavelength range''. However, by definition, the only correct form for the calculation of an average diameter from specific turbidity measurements is that of Equation (42). Equation (44) is valid only for very large diameters, where $K(\alpha_{\mathrm{av}}, m) = 2$, independent of particle size. In any other case if we try to estimate the two parameters (α_{av} and D_{32}) in Equation (44), ''over a range of wavelengths'', these estimates will be highly correlated. Their numerical values will depend on the wavelength range used and the D_{32} estimate will not, in general, correspond to the volume–surface-average of the true PSD.

5.3 Weight-average Diameters

For suspensions with small values of m (usually $m < 1.15$) and particle sizes corresponding to certain α values (i.e. for $m = 1.05, 3 < \alpha < 14$; for $m = 1.15, 3 < \alpha < 6$), the apparent diameters obtained from specific turbidity measurements are numerically close to the weight-average diameter, D_{w}. This average is essentially the only correct estimate of the particle size that can be obtained for polydisperse systems in these (m, α) regimes. If users know the value of m of their suspensions they can devise simple ways to obtain this average. For example, it has been observed[15] that the mean value of the apparent diameters from specific turbidities at 600 and 400 nm, obtained for a variety of polydisperse poly(vinyl acetate) latexes ($m \approx 1.1$) with different distributions (unimodal, multimodal) in the submicrometer regime, is numerically very close to the true weight average of the distribution. That means that for $m = 1.1$ the weight average from submicrometer particle suspensions can be estimated very simply, from two specific turbidity measurements at 400 and 600 nm. Similar heuristic rules could be derived for other suspensions with small m values.

Cheesman,[72] for example, suggested a technique in which the specific turbidity is measured at several wavelengths and the apparent diameter (D_{av}) is estimated for each wavelength. Then the corresponding α_{av} values are calculated ($\alpha_{\mathrm{av}} = \pi D_{\mathrm{av}}/\lambda_{\mathrm{m}}$) at each wavelength. The apparent diameter that gives α_{av} near the α value of the first point of inflection of the K_{scat} vs α curve is chosen to be the weight-average diameter (for $m = 1.1$, this α value was chosen 2.7 and for $m = 1.2$, it was 2.2). The apparent diameter selected this way in the polydisperse systems he studied was within 4% of the true weight-average diameter.

The observations of Cheesman can be explained theoretically. At the α value at the inflection point (see peaks of the first ripple of the y vs α curve in Figure 2) the value of y, for almost any value of m, is close to 4.5. If the weight-average diameter corresponds to this α value, then the α values for the individual particle diameters of the distribution are located around it and the value of y varies between 4 and 4.5. Hence in this technique, the wavelength is chosen such that the entire distribution is brought to an α regime where y is close to 4.0 and the apparent diameter is the weight-average diameter.

As has been pointed out,[44] the fact that the weight-average diameter of suspensions can be correctly estimated even though the PSD determination is impossible is a very useful property of the specific turbidity. It was suggested[44] that this property could be utilized for practical applications, in situations where following an average diameter is sufficient to monitor the progress of a process. An example would be on-line particle size measurements to monitor the progress of polymerization reactions. Gossen[23,46] and Gossen and MacGregor[24] used this suggestion and applied specific turbidity on-line to monitor weight-average diameters of poly(vinyl acetate) particles during latex production. The results reported[23,24,46,73] show good agreement between the weight-average diameters obtained by turbidimetry and those obtained by on-line DLS.

5.4 Other Applications of Turbidimetry

The dependence of turbidity on particle size can also be exploited in other ways than its conventional use in particle size determination. Kourti[15] suggested that simple

turbidity measurements at one wavelength can be used to monitor polymerization processes in order to detect the onset of several events, as for example the beginning of the reaction in latex systems (i.e. the end of induction period) or the onset of agglomeration. By following turbidity measurements at one wavelength during the emulsion polymerization of vinyl acetate in a continuous laboratory-scale reactor, Kiparissides et al.[9,10] could detect whether the reactor was operating under steady-state conditions or under oscillations. Turbidity measurements at 400 nm were used by Kourti[15] to follow qualitatively the effect of several variables on particle size during vinyl acetate emulsion polymerizations. Turbidity measurements at one or more wavelengths (and reduced to the same degree of dilution) can also be used for routine operations to monitor the progress of the reaction and detect any deviations from a known desirable path. Finally, Crawely et al.[74] discussed the use of turbidity measurements at several wavelengths in studies of crystallization, agglomeration and attrition.

6 PROCEDURAL DETAILS

6.1 Instrumentation and Forward Scattering

The turbidity of a suspension can be measured very easily in a laboratory or a plant environment. Very often spectrophotometers in the UV/VIS range are utilized for this purpose. A dilute suspension is inserted in the cell of the spectrophotometer. We have (Equation 46):

$$\tau_{\lambda_0} = 2.303\frac{A}{l} = \frac{1}{l}\ln\left(\frac{100}{T}\right. \tag{46}$$

where A is the absorbance reading, T is the percent transmittance at wavelength λ_0 and l is the optical path (i.e. width of cell). There are also reported applications where turbidity measurements at longer wavelengths, in NIR regime,[6,16,17,19,26] were used for particle size determination. Sometimes, certain modifications may be necessary[19] in the instruments used to measure turbidity so that forward scattering is rejected and theoretical calculations of turbidity can be legitimately compared with the measured values. This is because for the determination of particle size from turbidity measurements, it is assumed that the detector measures the attenuation of the beam of the source light. However, all the spectrophotometers measure the attenuated light from the source plus a certain amount of light scattered at small angles. Forward scattering will add error to the value of the true turbidity. Reports in the literature[34] mention that the larger the particles the greater is the possible discrepancy between the true and the measured (or apparent) turbidity, but for small particles and particles comparable to the wavelength the difference between the true and apparent turbidity should be minute. Bohren and Huffman[75] suggested that although conventional spectrophotometers are not usually designed to reject scattered light at small angles, such instruments may be adequate for scattering measurements if the particles are not too large. For monodisperse polystyrene latexes ($m = 1.2$) with diameters of 109, 312 and 1050 nm and turbidity measurements at wavelengths between 300 and 600 nm, they used a conventional spectrophotometer, suggesting that the forward scattering should not be significant. Walstra[76] suggested that sometimes errors attributed to forward scattering[18] were in fact due to extremely high optical densities that the investigators had included in their results.

The brief analysis that follows illustrates the consequences of the error added to the value of the true turbidity due to forward scattering. The effect that an error in the measured turbidity value has on the estimated particle size depends on the turbidimetric technique used and the (m, α) values of the system and it cannot be generalized. The turbidity ratio utilizes two turbidity measurements at different wavelengths, therefore the error due to forward scattering is introduced twice in this method, but only once in the specific turbidity. In Figure 5 we plot[15] as a function of α, for two different m values, the percentage error in the estimated diameter in monodisperse suspensions for a 3% error in the measured specific turbidity. Note that the effect changes with the (m, α) combination. For $m = 1.2$ and α values near the specific turbidity maximum (which for $m = 1.2$ occurs at $\alpha = 7.33$), the error becomes very large. However, for α

Figure 5 Percentage error in the estimated particle diameter of monodisperse suspensions plotted as a function of α for $m = 1.1$ and 1.2 when there is a 3% error in the specific turbidity measurements.

values less than 4.0 the error in the diameter is the same for $m = 1.1$ and 1.2, and it is approximately 4.0%. For water medium ($n_m \approx 1.33$), a value of $\alpha = 4$ corresponds to $D/\lambda_0 \approx 1$ ($\alpha = 4 = \pi D n_m/\lambda_0$), which means that for particles smaller and comparable to the wavelength the error is small. Therefore, if the error due to forward scattering introduces a 3–4% error in specific turbidity, then for particles comparable to λ_0 the effect on particle size should not be significant, and this would explain the observations reported by various workers. A final note on Figure 5: it demonstrates that a 3% error in the specific turbidity measurements may cause a very large error in the estimated size for α values near the peaks or the valleys of the K_{scat} vs α curve. This is due to the light scattering behavior and has nothing to do with the source of the error (i.e. this 3% could be due to either a wrong solids fraction measurement or to forward scattering, and would have the same effect on the estimated size).

Errors in turbidity measurements due to forward scattering are discussed in a number of references, where suggestions are given for the modification of the spectrophotometers.[6,18,20,30,49,76–78] Also, several empirical approaches have been suggested to account for the difference between true and apparent turbidity.[20,66] For example, a correction factor (R) can be estimated[20] for several suspensions with known particle diameters; R is equal to the ratio of the measured to the theoretically expected turbidity. This factor can then be used for unknown suspensions, but with (m, α) values in the same range for which it was estimated. In another approach, a calibration was used[66] to relate apparent specific turbidity with the true particle size for large latex particles where forward scattering is significant.

Users can assess the accuracy of the turbidity measurements of their spectrophotometers by comparing the experimental values with theoretically calculated values for monodisperse suspensions with known diameters, covering the range of (m, α) values that they plan to analyze. Before proceeding to any modifications one should judge whether the accuracy is satisfactory for the purpose of the study to be carried out using the turbidimetric results. For example, if the purpose of the study is to use the method as a reproducible and inexpensive way to monitor particle size during a reaction, then the accuracy of the spectrophotometer with no modifications may be satisfactory, and similarly if the objective is to detect the qualitative effect of various parameters (emulsifier, impurities) on the particle size of the latex. For other applications that require more accurate determinations of larger particles, one may consider modifications of the spectrophotometer and the use of a correction equation[76] that accounts for the angle of acceptance of the detector for the calculation of the scattering coefficient. Kourti[15] used two spectrophotometers without modifications for diameters up to 400 nm and suspensions with $m = 1.1$ and 1.2: a Hewlett-Packard Model 8450A at wavelengths of 350–700 nm and a bandwidth of 2 nm and a Bausch and Lomb (now Spectronic Instruments) Spectronic 20 at wavelengths of 380–580 nm and a bandwidth of 20 nm. The accuracy of the method was tested by estimating the size of monodisperse suspensions with known diameters and also by comparing the size estimated by turbidimetry with that measured by EM and DLS. For numerous unknown samples, the diameters estimated by turbidimetry were in very good agreement with those measured by DLS and EM. Forward scattering did not introduce any problems.

Gossen and MacGregor[24] used for on-line measurements in a pilot-plant environment a Bausch and Lomb single-beam Spectronic 20 equipped with a cylindrical Pyrex flow-through cell with a 1 cm pathlength, without any modifications for forward scattering. The incident beam had a bandwidth of 20 nm and the wavelength was 400 nm. Weight-average diameters up to 200 nm obtained during latex production were in very good agreement with weight-average diameters obtained by on-line DLS,[73] and a change in D_w of the order of 10 nm was detectable. The accuracy of the results was considered satisfactory for their objective to monitor changes in the particle size due to process disturbances.

6.2 Refractive Indices of the Particles and the Medium

Turbidity is a very strong function of the optical properties of the particle suspension, that is, the ratio of the refractive index of the particles to that of the medium, m, and the refractive index of the medium, n_m. The latter is used for the calculation of λ_m and consequently the calculation of α. For the correct determination of the particle size the values of these properties must be accurately known. The values of the refractive indices for different materials can be found in relevant handbooks.[79] Refractive indices can also be directly measured, or estimated using a combination of techniques as described below.

Llosent et al.[27] used a Bellingham Abbé 60 refractometer to measure the refractive index of latex particles, n_p, required to calculate m for their work. The refractive index of the polymer film was measured at several wavelengths. They then used the measured values to estimate the constants for a Cauchy[80] equation that expresses n_p as a function of the wavelength λ_{0i} (Equation 47):

$$n_p(\lambda_{0i}) = A + \frac{B}{\lambda_{0i}^2} + \frac{C}{\lambda_{0i}^4} \tag{47}$$

This equation was subsequently used to calculate n_p at other wavelengths.

If the value of the refractive index of the medium n_m is known but n_p and therefore m are not known, it may be possible to estimate m directly using a combination of

techniques. Kourti[15] suggested that, since turbidimetry is very sensitive to the value of m, it is probably the best method to ''estimate'' the values of m as a function of wavelength for a specific suspension. Suppose we wish to estimate the value of m for suspensions of polybutadiene particles in water. Using a monodisperse suspension of polybutadiene particles in water with known diameters (estimated by EM or DLS), the scattering coefficient and therefore m can be calculated from the specific turbidity measurements at one wavelength (provided n_m is known). By measuring specific turbidities at more wavelengths one can estimate the dependence of m on wavelength. The advantage of this approach is that the value of m for a particular suspension is measured in the environment in which it will be used. This may be more meaningful than, say, using a latex film to measure the refractive index of particles and dividing by the refractive index of medium. Once m has been measured it can be used for suspensions of the same material (i.e. polybutadiene in this example), but of course for any particle sizes or PSD. DLS is an excellent method for this purpose because the particle sizes can be measured in suspension and for monodisperse particles DLS is independent of the refractive index. Another method to determine optical constants would be angular light scattering.

Sometimes the medium may not be a clear substance but may have additives. In latex samples, for example, emulsifier may be added to the water medium, or monomer may be dissolved in it if the samples are withdrawn at low monomer conversions. In these cases the refractive index of clear water cannot be used. The refractive index of the medium for a given concentration of water-soluble monomer (or other substance present in it) can be read directly from a calibration curve of refractive index as a function of the concentration of monomer in water. Such calibration curves can be easily constructed from refractive index–concentration increments obtained from differential refractometers. In high dilutions the effect of monomer on the refractive index of the medium is usually negligible.

6.2.1 *Inhomogeneous Particles/Latex Particle Applications*

Sometimes the particles in the suspension may not be homogeneous. Examples from latex systems are carboxylated particles that swell in water, particles swollen with monomer in latex samples withdrawn at low conversions and particles produced by core and shell polymerizations. There are several issues related to determining the optical properties of such particles and research is active on light scattering by inhomogeneous particles.[81–83]

For monomer swollen particles, or particles produced by core and shell polymerizations, one approach is to calculate the value of m by treating the particles as coated spheres. For coated spheres the refractive index ratio can be calculated as $m = m_1 v_1 + m_2 v_2$, where m_1 is the ratio of the refractive index of the core to the medium and v_1 is the volume fraction of the core; m_2 and v_2 are the corresponding values for the coating. ($v_1 + v_2 = 1.0$). This approximation is not very accurate for thin coatings. In the above approach, for monomer swollen polymers, the volume fractions of the monomer and polymer are treated as core and coating respectively. It should be emphasized that this is an approximation, and the true morphology of monomer swollen particles may be different than a core and coating approximation. Bohren and Hoffman[75] also presented an algorithm to calculate the scattering functions of coated spheres (consisted of homogeneous core and homogeneous coating of uniform thickness) and they discuss the limitations of this algorithm, in general, for anisotropic spheres. For very accurate calculations, these approximations to estimating the value of m for core and shell particles must be checked experimentally. This can be done as mentioned earlier by using another method (i.e. DLS) to estimate the particle size and then using turbidimetry to estimate the value of m for particles with known polymer composition. The above calculations should be performed on monodisperse suspensions. A calibration curve could then be constructed to give the value of m as a function of the polymer composition in the particle. If DLS is used to verify the particle size of monomer swollen particles, the same degree of dilution must be used to make sure that the same particle size is measured (because monomer is dissolved in water and extracted from the particle with high dilutions).

For monomer swollen particles and carboxylated particles that swell in water, both the density and the refractive index depend on the degree of swelling and appropriate corrections should be made. In monomer swollen particles, the amount of monomer associated with the particles (and therefore the refractive index of the particles and the medium) depends on the conversion, the solubility of monomer and the degree of dilution of the original sample.

Latex produced by multicomponent polymerization is also a case where the calculation of the refractive index of the particles may present difficulties. The refractive index depends on the polymer composition and may change during the reaction due to composition drift. Therefore, calibration may be needed to relate the refractive index of the particles to their composition (by taking into account the conversion of the monomers at the time of sampling). When monitoring particle growth with on-line turbidimetry during multicomponent polymerizations, on-line gas chromatography can be utilized to provide

information on the composition of the particles. The refractive index can then be calculated from the particle composition utilizing some type of calibration. On-line densitometry combined with on-line gas chromatography can provide information on the particle volume fraction, ϕ. More details on this topic can be found in Kourti.[15]

6.3 The Choice of the Wavelengths

As discussed earlier, the successful determination of the PSD or of an average particle size of a suspension depends on the m and α values of the suspension and the turbidimetric technique used. The refractive index of the medium and therefore the value of m of a suspension can be altered by adding other substances to the medium [e.g. glycerol[5,16]] provided that these substances do not affect the particle size. The range of α values covered by the PSD can also be manipulated by changing the wavelengths at which the turbidity measurements are taken. As a general rule, wavelengths widely separated from each other should be used when the estimation of the full PSD is required. In this way the range of α values covered by the PSD changes significantly from one wavelength to another (the y exponent changes) and the probability of the turbidity being proportional to the same moment of the PSD at both wavelengths is reduced. It should be noted, however, that when wavelengths widely separated from each other are used, the value of m at each wavelength must be accurately known; using a constant m may result in false estimates.[15] If only one value for m, estimated at, say, λ_0', is available and must be kept constant for all the wavelengths, then wavelengths on either side of λ_0' (i.e. both shorter and longer) and as close to λ_0' as possible must be used.

To keep wavelengths widely separated, several workers chose one wavelength in the UV/VIS range and one in the IR region. The first (1.7 μm)[16,17] and the second (2.22 μm)[19] IR transmission windows for water have been the choices for long wavelengths. Most workers have avoided wavelengths below 400 nm where some particles may absorb light and wavelengths where the medium absorbs light.

Eliçabe and Garcia-Rubio[62] used wavelengths in regimes where particles absorb to resolve the PSD for a computer-simulated polystyrene latex example, where clear water was assumed to be the medium. The resolution of the PSD was improved. However, in practical situations for latex particle size analysis, it is preferable to avoid working at short wavelengths where absorption occurs (e.g. the styrene ring absorbs at 269.5 nm). In latex samples withdrawn at low monomer conversions, residual monomer which absorbs light at certain short wavelengths may be present in the particles and extracted owing to dilution in the medium. As a consequence, if particle size determination is attempted at these short wavelengths without accounting for the distribution of the absorbing monomer between the medium and the particles, the results may be questionable. However, calculating the monomer distribution is tedious and requires a knowledge of conversion, partition coefficient of the monomer between the water and the polymer phase and the degree of dilution. It is clear that using short wavelengths is not practical if the objective is to follow particle growth during the reaction.

6.4 Preparation of Samples

In particle size determination by light scattering methods, it is usually assumed that the scattering by an array of particles is incoherent (the particles are randomly positioned in space to avoid mutual polarization) so that the scattering functions corresponding to an isolated particle may be used, and also that there is no significant multiple scattering. These conditions are practically met[33] when turbidity measurements are taken with sufficiently dilute suspensions. In practice this is achieved by diluting the suspension and working at a concentration range where the turbidity, at the shortest wavelength to be used, varies linearly with the particle concentration. Figure 6 shows how turbidity changes with concentration. The shorter the wavelength, the lower is the concentration of suspended solids required to avoid multiple scattering.

The fact that the sample needs to be diluted may have an effect on the particle size in certain cases. For example, in latex samples withdrawn at low conversion, polymer particles swollen with monomer may change size by changing the degree of dilution, and this should be taken into account. Also, for latex particles stabilized

Figure 6 Turbidity plotted against solids concentration in the sample: linearity check.

by ionic or nonionic emulsifiers or other groups, the user must be careful to dilute the sample without risking destabilization. Some emulsifier (the same as the one used in the latex production) must be added to the diluting medium to prevent destabilization. Samples prepared in this way remained stable for a long time;[15] turbidity measurements taken 3 years after the samples were prepared showed no difference within experimental error with measurements taken for those samples when they were freshly prepared. Kourti[15] discussed in detail other considerations for latex particle size determination, for both off-line and on-line applications.

6.5 Particle Volume Fraction for Specific Turbidity

Particle volume fraction is measured by gravimetric analysis. The weight of the dry solids per cubic centimeter (c, g cm^{-3}) is measured and converted to volume fraction using the density of the particles (ρ, g cm^{-3}); $\phi = c/\rho$. Particle volume fraction is usually measured on undiluted samples. The particle volume fraction corresponding to the diluted sample on which the turbidity measurement is taken is calculated by taking into account the degree of dilution. Therefore, the degree of dilution must be known very accurately. Particle volume fraction for on-line applications can be measured by densitometry.[21,23,24]

7 EFFECT OF ERRORS ON THE ESTIMATED PARTICLE SIZE AND PARTICLE SIZE DISTRIBUTION

The determination of the particle size or PSD of a suspension using turbidimetry involves measurements and assumptions. Errors in the measurements and uncertainty in the assumptions will have a minor or a major effect on the estimated size. The sources of errors can be grouped as follows:

- Experimental errors in measurements: these involve random measurement errors and errors due to forward scattering (bias) in the turbidity measurements. For specific turbidity methods there are also errors in the calculation of the solids volume fraction due to dilution, error in gravimetric analysis and uncertainty in the value of density of the particles.
- Uncertainty in the m values and the dependence of the m on the wavelength: m is required for the theoretical calculation of the scattering functions.
- For polydisperse samples, error in the assumptions related to the PSD: either the form of the PSD has to be assumed or the number of discrete points, their range and the value of the smoothing parameters.

The sensitivity of the estimated particle size to such errors has been investigated by several workers. The results are briefly summarized in the following sections.

7.1 Error in Measurements

The effect of measurement errors on the estimated particle size depends on the technique used (specific turbidity or turbidity ratio) and on the (m, α) values of the system and cannot be generalized, as illustrated in the following. Kourti[15] reported an average error of 0.4% in the repeatability of transmittance readings. Such an error is translated to an average 2% error in specific turbidity. For the (m, α) values used, with $m = 1.1$ and $\alpha < 3.5$ this error would translate to a maximum error of 2% in the particle diameter for monodisperse suspensions. If a different technique, say turbidity ratio, was used for the same (m, α) regime, then from a small bias of +0.5% on the transmittance readings at both wavelengths (the same bias would be the case due to forward scattering) the error in the particle size for monodisperse particles can be 2–3%. For the same size regime, if instead of the bias the error was random ($\pm 0.5\%$), then the error in the particle size can be as large as 9%. Because the effects of turbidity measurements on particle size cannot be generalized over (m, α) values, a good practice for users would be to construct a curve such as that in Figure 5 for the m value of the suspensions with which they plan to work. The effect of a certain percent error in specific turbidity (or turbidity ratio) on the estimated particle diameter can be calculated with simulations for a wide α range. Then, by changing the value of α used (by changing the wavelength), they can move the system to a regime where measurement errors would not affect the particle size significantly.

The effect of measurement errors on the estimated PSD in polydisperse systems was the subject of a detailed study[15,32] and it has been shown to depend on the technique used (specific turbidity or turbidity ratio) and on the (m, α) values of the suspension. As discussed in section 4, the estimation of full PSD is impossible within experimental error in some (m, α) regimes. However, in these regimes, if specific turbidity is used, an average diameter can be correctly estimated and the effect of measurement error on this average diameter is not large. In regimes where only the weight-average diameter can be estimated, for a random error of $\pm 3\%$ in specific turbidity at three wavelengths, the maximum error was for a weight average 5%. As a comparison the maximum error for the number average in these regimes was 40%.[15]

7.2 Error in the Value of the Refractive Index Ratio, m

Kourti[15] studied the effect that errors in the value of m have on the estimated PSD. It was concluded that

turbidimetry is sensitive to such errors but the magnitude of the effect on the estimated PSD depends on the (m, α) values of the suspension. In certain (m, α) regimes, the effect that the error in m has on the estimated parameters of the PSD is comparable to the effect of turbidity measurement errors, whereas in others it is much higher. In regimes where the y exponent does not change significantly with the particle size, the errors in the value of m had a larger effect on the estimated size than turbidity measurement errors. Therefore, observations reported in the literature on the magnitude of this effect cannot be generalized for any (m, α) values. For example, the observation of Wallach and Heller[7] that "the error of the disregard of the dispersion of m is less that experimental error" was simply a coincidence of the (m, α) values of the system with which they were working. Whenever there is uncertainty in the value of m of the suspension to be analyzed, a sensitivity analysis should accompany the results, to indicate the degree of confidence. Alternatively, the results should be corroborated with another method.

Sometimes, the dependence of the refractive index of the medium, n_m on the wavelength is known, but only one measurement for the refractive index of the particles, n_p, at one wavelength λ_0' is available. If this is the case, it is recommended that a constant m (calculated at λ_0') is used at all the wavelengths, and not a variable m calculated with constant n_p and wavelength-dependent n_m. For water medium, a wavelength-dependent n_m decreases with longer wavelengths and using constant n_p will force m to increase with longer wavelengths (when it is expected to decrease); this in turn means significant errors when analyzing real data since the estimated particle size moves in the opposite direction to the true value. Finally, when a constant value of m is used, the error is smaller if the turbidity measurements are taken at wavelengths both shorter and longer and as close as possible to the one at which m was measured.

In all cases, however, if the wavelength-dependent n_m is known, it should be used to calculate the value of λ_m and therefore α for the scattering coefficient calculation.

7.3 Error in the Assumed Distributional Form

The main criticism in the literature about approaches that attempt to recover the PSD by assuming a type of the distribution (i.e. log-normal, Gaussian, etc.) is that the assumed distribution may be very different from the true one. When a distributional form is assumed, a constraint (i.e. the shape of the distribution) is forced upon the solution. The expected result is a PSD with the assumed shape that will envelope the true distribution; the details of the true PSD are not expected to be resolved. The estimation of the location of the main body of the distribution is therefore the most satisfactory result expected in this case.

The error introduced in the estimated PSD when the assumed distributional form is different from the true one has been studied either experimentally or with simulated cases by several workers. Wallach and Heller[7] tried to estimate the PSD of three suspensions with positively skewed, negatively skewed and symmetrical distributions, using the turbidity ratio method and assuming a distributional form which can describe only positively skewed distributions. In the cases of negatively skewed and symmetrical PSDs, the estimates of the parameters chosen to describe the distribution had a significant error; however, Kourti[15] reported that a careful examination of those results showed that the estimated PSD enveloped (i.e. recovered correctly) the main body of the true distribution. This behavior was expected since the polydispersities of the three synthesized distributions and of the assumed distribution were very small; no distributions with very long tails to small or large particles were studied.

In an extensive simulation study, Kourti[15] investigated the error introduced in the estimated PSD when the shape is assumed to be log-normal. Specific turbidities were calculated (at 400, 500 and 600 nm) for several polystyrene suspensions of submicrometer particles with several types of continuous distributions: positively skewed, negatively skewed, symmetrical, bimodals with broad peaks and overlapping tails. The polydispersities were from 1.04 to 1.9. Then, from these calculated specific turbidities and assuming a log-normal form, the PSD of the suspension was re-estimated. The following conclusions were drawn that are valid for the estimation of the PSD (using the specific turbidity method) of suspensions of submicrometer particles, excluding the Rayleigh regime where only D_τ can be estimated and the (m, α) regimes where specific turbidity can only give D_w:

- When the true distribution is continuous with no long tails to either small or large particles, the estimated distribution with a log-normal assumption will cover the main body of the true PSD when plotted on a number basis.
- On a weight basis the main body of the true distribution will be covered by the estimated log-normal distribution, in all cases, even when the true PSD has long tails.
- The weight-average diameter of the distribution estimated with a log-normal assumption is very close to the true weight average of the suspension, even in cases that the true distribution is significantly different from a log-normal shape. For the cases studied the weight-average diameter of the PSD estimated when assuming a log-normal form (on a

number or weight basis) was, in general, within 1.0% of the weight average of the true PSD.

These conclusions are corroborated by experimental results reported by Haseler[19] for submicrometer polystyrene suspensions. They also agree with the observations of Yang and Hogg.[20] These authors also studied experimentally the error on the estimated PSD when the shape of the true distribution is different from the assumed log-normal form. The estimated distribution was compared with the true one on a weight basis; the distributions studied were broad, covering particle sizes from 0.1 to 10.0 μm. They found that "the estimated distribution conformed closely to the central portion of the true distribution (on a weight basis) and was not strongly biased towards either of the tails".

It should be noted that when using Equation (31) to estimate f_j for diameter $D_j (j = 1, 2, \ldots, P)$, instead of assuming a form for the PSD, there are also assumptions involved. These include the choice of the parameter in the regularization algorithm and the number of points to which the PSD will be discretized and the location of the D_js. The number of points depends on the available number of turbidity measurements at different wavelengths. For a study on the effect that the number of discrete points at which f_j is estimated has on the estimated PSD, readers are referred to Eliçabe and Garcia-Rubio.[62] In that study the true distributions were all simulated continuous distributions.

There is also the question of whether there is an advantage in proceeding with collecting more wavelengths and trying to estimate the distribution using Equation (31). In the case of continuous unimodal distributions, the resolutions of the two techniques under experimental error seem to be comparable; an assumption of a log-normal shape that will provide the main body of the true PSD and the true D_w may be sufficient for most routine applications in the submicrometer and lower micrometer region.

7.3.1 The Resolution of Bimodal Distributions

Regularization methods have the potential to recover the PSD without assuming any shape, if the true distribution is a bimodal one with two broad peaks, such as that shown by the histogram in Figure 7. Eliçabe and Garcia-Rubio[62] resolved such a simulated distribution where the particle diameters covered a very wide range from 50 to 2550 nm; in that study wavelengths in the absorption range were included for the turbidity measurements. For such bimodal distributions, the regularization methods have the capability (provided that there are enough turbidity measurements) to uncover the true shape whereas the log-normal assumption will always produce an envelope around the main body, as shown in Figure 7. Distribution I

Figure 7 Bimodal distribution as resolved by a log-normal assumption. Case I: the estimated log-normal distribution (continuous line) and the true distribution (histogram) are located between 0 and 0.8 μm ($D_0 = 0.0$). Case II: the estimated log-normal distribution (dashed line) and the true distribution (histogram) are located between 0.4 and 1.2 μm ($D_0 = 0.4$).

in Figure 7 shows the distribution (on number basis) estimated with a log-normal assumption for polystyrene suspensions ($m \approx 1.2$) where the true distribution (shown by the histogram) was in the size range between 0.0 and 0.8 μm ($D_0 = 0.0$). Distribution II is the log-normal PSD estimated when the size range for the true distribution was between 4.0 and 1.2 μm ($D_0 = 0.4$). Note that although the two histogram distributions have the same breadth (0.8 μm), in case II the distribution has a smaller polydispersity (since the average size is larger). Note that in case I the estimated log-normal distribution tends to envelope only the larger particles of the true distribution, whereas in case II it uncovers the correct range but of course cannot resolve the bimodal shape.

When dealing with bimodal distributions one should keep in mind that the contribution of small particles to the value of the specific turbidity could be totally obscured by the contribution of the large ones, depending on their α values (relative to the α value location where the peak of K_{scat} occurs). As an example, assume a polystyrene suspension ($m \approx 1.2$) with a bimodal distribution which consists of two monodisperse populations with $D_1 = 0.6$ μm and $D_2 = 0.1$ μm, and where the number of small particles is 10 times the number of the large ones ($N_2/N_1 = 10$). The contribution of the small particles to the total specific turbidity at 400 nm is only 0.46%. Hence the presence of small particles will cause less disturbance than the experimental error even though there are 10 times more small than large particles. In such a case it is not expected that the regularization methods will produce the correct solution within experimental error.

Wallach and Heller[7] suggested using combinations of two distributions with the same form to describe distributions that are negatively skewed, or bimodals. A combination of two-parameter distributions (say two log-normal distributions) requires the estimation of five parameters ($D_{1g}, D_{2g}, \sigma_1, \sigma_2, N_2/N_1$). At least five specific turbidity measurements at wavelengths far from each other are required for this estimation if the particles are in the submicrometer range. These parameters are expected to be very highly correlated and therefore the solution to be sensitive to experimental error. A good solution may be obtained in cases where the contribution of the distribution of the smaller particles to the overall specific turbidity is large; otherwise the large particles will always obscure the small particles.

Readers should keep in mind that in general, bimodal distributions (except those where the distance between the modal diameters of the two populations is large compared with the breadth of the two populations) are very difficult to resolve with most particle sizing methods. Using EM, for example, a large number of particles must be counted, sometimes at different magnifications in order to resolve the distributions successfully. DLS will usually result in distributions weighted towards larger particles. For bimodals where the distance of the two modal diameters is large compared with the breadth of the distributions, one can usually determine very successfully the particle sizes involved in the two populations (by EM and sometimes by DLS), but it is difficult to estimate the relative number of particles in the two populations. In such cases, if the diameters involved are known very accurately from EM ($D_1, D_2, \ldots, D_n$), then using a sufficient number of turbidity measurements one could estimate the relative number of particles ($f_1, f_2, \ldots, f_n$) (from Equations 31 and 39). Again, in order to obtain reasonable estimates, the small particles should weigh significantly and the distribution must be in an (m, α) regime where specific turbidity measurements do not simply result in the same apparent diameters (otherwise all combinations resulting in the same average are possible solutions).

8 ON-LINE PARTICLE SIZE DETERMINATION USING TURBIDIMETRY

As early as 1973, Hamielec and Wright[84] suggested using turbidimetry for on-line latex particle size determination. The configuration of a sampling device for on-line measurements of the PSD of poly(vinyl acetate) latexes using turbidimetry was suggested from that laboratory in 1976.[85] On-line turbidity measurements in fully automated systems have been reported for poly(vinyl acetate) latexes by Kiparissides et al.[9,10] and Zollars[11] but no quantitative results from on-line particle size determination were reported by these workers. Haseler and Parkin[6] used on-line turbidity measurements to monitor the growth of silver bromide in a ripening process. The ripening suspension was circulated continuously in an undiluted state through a thin cell.

In all of the applications mentioned above only turbidity was measured on-line. An experimental set-up to combine on-line determination of the particle volume fraction with on-line turbidity measurements, required for on-line specific turbidity measurements, was first suggested by Pollock.[86] However, no results were reported on particle sizing, probably because he faced some problems with that set-up. A simulation for on-line latex PSD determination in continuous latex reactors was presented by Bradolin and Garcia-Rubio.[22]

Raphael and Rohani[26] described a device that could be used on-line to measure the mean particle size in continuous precipitators or crystallizers. The solids concentration for this set-up is assumed to be known and no measurements on the particle volume fraction are taken on-line. This device was not tested on-line, however, for continuous production; the measurements reported were from spot samples. These samples were diluted in a vessel from which the diluted sample is pumped through the device and turbidity measurements are taken.

A serious disadvantage of some of the set-ups suggested for on-line latex particle size determination[9,10,11,22,86] is that they require a continuous flow of diluted latex through the spectrophotometer. For specific turbidity measurements this means that a known amount of latex is continuously mixed with a known amount of diluent. Both the latex and diluent have to be pumped at constant flow rates. This in turn requires that a very small amount of latex be pumped at the exit of the reactor, at flow rates as low as $10\,\mathrm{mL\,min^{-1}}$, for long periods of time. A peristaltic pump tried by Gossen[21] for this set-up failed owing to coagulation of the latex due to high shear and chemical attack of the tube by the monomer. Other types of pumps tried in the same laboratory also failed.[23] Another problem with continuous dilution of the latex is that an enormous amount of waste (very dilute latex) is created that requires treatment before disposal. This would cause problems in large-scale operations. The set-up suggested earlier from the same laboratory[85] utilizes discrete sampling, but it has serious disadvantages.[23]

A system suggested by Gossen[23,24] measures both solids fraction and turbidity on-line, utilizes discrete sampling, is mechanically simple, has a short cycle time and high accuracy and it is set up such that thorough cleaning of the sampling element is performed after each sample. This sampling device was used for the on-line

application of specific turbidity to monitor particle growth during poly(vinyl acetate) production in continuous pilot-plant reactors. Samples were taken at discrete intervals of 5 min. Results were reported for a period of 10 h. The weight-average diameters estimated by turbidimetry showed excellent agreement with results from on-line DLS.[73] These results, obtained by Gossen, represent the first published successful effort[24,46,73] to combine on-line turbidity and density measurements and to monitor, on-line, weight-average diameters during latex production in pilot-scale reactors, in a fully automated manner. Details on the set-up and an error propagation analysis study can be found in Gossen.[23,24]

9 OTHER CONSIDERATIONS

9.1 Choice of the Methods

It is a well-established perception in particle size analysis that there is no method which can be successfully utilized for every application. The effectiveness of each particle sizing method depends on the special needs applicable to each case. The selection of the method is a compromise between accuracy, cost, speed of analysis and robustness of the instrument in the plant or the laboratory environment. This section gives some examples that might help users decide if turbidimetry is suitable for their applications.

There are cases where an accurate estimate of the full PSD is required. In such cases the time required for analysis and the cost of the method are not usually an issue. Examples of such cases are the evaluation of a new process and the PSD of the new product, the study of the effects of various parameters on particle size in a set of designed experiments and the detailed study of a nucleation process where the PSD reflects the mechanisms that take place. For such cases more time and effort are usually spent than for routine particle size analysis and more than one particle sizing methods and/or alternative approaches to the same method are used. EM will provide measurements of the sizes involved in the distribution, and will give an indication of the type of the distribution (i.e. detect the presence of two populations, etc.). However, resolving the full $f(D)$ with EM is a tedious task because a very large number of particles need to be photographed and counted from representative parts of the sample. Specific turbidity can be used to obtain a correct estimate of the weight-average diameter of submicrometer particles if the (m, α) regimes do not allow for the full PSD determination. If the (m, α) values allow for the full PSD determination, then regularization methods, where no fixed shape of the distribution is assumed, should be tried first. If these methods show that the shape is smooth and the log-normal assumption is sufficient, then this assumption can be used for subsequent routine analysis. DLS could also be used to corroborate the results for submicrometer particles. Alternatively, sedimentation field fractionation[87–89] could be used; this method would be especially useful in cases where EM cannot be used either because the particles change size when they are measured dry or they need special treatment for EM measurements.

Sometimes only routine-type checks are needed and an average of the PSD or the log-normal assumption that will provide the main body of the distribution may be sufficient. Turbidimetry could be used as a fast, inexpensive technique for such applications.

In some cases only qualitative information is required, for example when studying qualitatively the effect of certain process parameters on the particle size. In such cases almost any technique can be utilized provided that the same quantity is followed and that this quantity is sensitive to small changes in the particle size. For example, specific turbidity can be used to follow a weight-average diameter or DLS to follow the intensity-average diameter. It is important that the same method be used to follow the same average throughout the study because, as discussed in the next section, different methods are theoretically directly related (and therefore are more sensitive) to different averages of the PSD. Other applications where the dependence of turbidity on particle size can be qualitatively exploited is to use turbidimetry as a detection system (as discussed in section 5.4) to detect the onset of agglomeration or reactor oscillations in latex production.

When the product is suspected to contain two populations of particles with different sizes (e.g. large and small particles due to a secondary nucleation), the small particle population will be clearly detected by EM or chromatographic (i.e. size separation) techniques. Size separation techniques are very powerful in detecting small-particle populations. If the contribution of the small particles to the overall turbidity is significant then the bimodal distribution can be resolved by turbidimetry using regularization algorithms (i.e. solving for PSD without assuming a fixed shape). Otherwise, specific turbidity will only provide the weight-average diameter for a bimodal suspension of submicrometer particles.

When choosing a method for on-line measurements, one must consider several factors: the type of process (batch or continuous), the purpose of the measurement (is it routine analysis where we are satisfied with an average size, or do we need accurate PSD determination), the required sampling frequency and analysis time of the method, the cost relative to the expected accuracy and the reliability and robustness of the method in the

plant environment. Turbidimetric methods utilize the fastest measurements (light is used as a probe). As a comparison, fractionation (separation) techniques cannot provide any estimate of the particle size or the PSD until the fractionation is completed.

It is clear that users must consider several factors before choosing the technique or a combination of techniques that are most suitable for their needs. This requires a good knowledge of the process, the product and the capabilities and limitations of the technique. Finally, quoting Groves,[90] "the validity of the data need have no direct relation to the cost of instrumentation".

9.2 Corroboration of Results

When another particle sizing method is used to corroborate results from turbidimetry, this second method must be chosen carefully. In general, when comparing results on the full PSD from different methods, the size range to which each of the methods is applicable, their resolution, the effects of errors on the estimated size and any assumptions introduced in each technique should be considered. This holds even when comparing results from two different turbidimetric techniques (i.e. turbidity ratio and specific turbidity). Erroneous conclusions may be obtained, as illustrated with the following examples.

The size range to which each of methods is applicable should be considered. Wales[58] used particle size measurements from a Coulter Counter instrument to corroborate results from turbidimetry. Some discrepancies were observed between the two methods. From a detailed discussion[15] of his work it became clear that in particle size regions where both Coulter Counter and turbidimetry are capable of providing a valid estimate of the PSD the two methods compared favorably. The discrepancies observed for suspensions with PSDs in the lower submicrometer range were not due to forward scattering as originally claimed.[58] Rather, they were due to the fact that the Coulter Counter instrument could not detect very small particles (in the lower submicrometer region) and specific turbidity for the (m, α) values of those suspensions could only provide a correct D_w and not the full PSD. Discrepancies between turbidimetry and Coulter Counter results were also observed by Walstra.[16] The Coulter Counter instrument should not be used to corroborate results from other techniques when dealing with distributions of small particle sizes (i.e. lower submicrometer particles) or PSD with tails of small particles.

Any assumptions involved in the methods should be considered. Some average diameters obtained by various techniques can be directly derived from the underlying theory whereas others depend on the validity of certain assumptions. Only quantities estimated directly from theory should be compared. For example, DLS measures an "average diameter" that corresponds to the mean diffusion coefficient of the suspension. With the assumption that the distribution of the diffusion coefficients is Gaussian, a PSD and its corresponding weight-average diameter can be calculated. However, although the estimated mean diffusion coefficient is correct, this weight-average diameter is not always equal to the true weight average of the suspension. In contrast, the weight average measured by turbidimetry is numerically close to the true weight average for most submicrometer suspensions. In another example, some DLS instruments utilize the Rayleigh–Gans approximation to convert distributions from an intensity basis to a weight basis. This approximation is not valid for very large particles and may cause serious errors in the calculation of the PSD on a weight basis for broad distributions or widely spaced bimodal distributions, even if the distribution estimated on an intensity basis is correct.

10 CONCLUSION

Turbidimetric particle sizing methods are experimentally simple, robust and have very good reproducibility and potential for on-line applications. They have been applied for the estimation of the PSD or an average size to a variety of particle suspensions (Table 1) with diameters ranging from 0.035 to 50 μm.

Specific turbidity can be used for reliable estimates of the average particle size and of the PSD of a suspension for a wider range of particle sizes than the turbidity ratio or the wavelength exponent techniques. This is because specific turbidity involves two independent measurements of the particle size via two different properties of the suspension (turbidity and solids volume fraction), whereas the other turbidimetric techniques are based on turbidity measurements only. Therefore, if the volume fraction of particles in the suspension can be measured, specific turbidity should be the turbidimetric technique of choice. The turbidity ratio or the wavelength exponent method should be used only if the particle volume fraction is unknown.

Because of the light scattering behavior, turbidimetric methods are not theoretically expected to provide information on the full PSD in many situations. In order to decide the type of information about the particle size (average size or full PSD) that can be extracted from any turbidimetric method, one must consider both the value of the refractive index ratio (m) of the suspension and the α values covered by the distribution. The same PSD that can be successfully estimated for one system may be impossible to estimate for another system with a different m value.

There are a few critical combinations of (m, α) values in turbidimetric analysis for nonabsorbing particles:

- suspensions of submicron particles and values of m smaller than 1.15;
- suspensions with any value of m and very small particles ($\alpha < 0.5$);
- suspensions of very large particles ($\alpha > 150$).

In these regimes, the turbidity ratio and the wavelength exponent method should be avoided and only specific turbidity should be used. If the particle volume fraction is not known, then for suspensions in the above regimes it is better to choose a sizing method other than turbidimetry. Furthermore, reliable information on the full PSD may be very difficult to obtain in the above regimes, by any turbidimetric technique, within experimental error. Specific turbidity, however, will give a very good estimate of meaningful averages of the PSD: the weight-average diameter in the first case (from the mean value of the apparent diameters at 400 and 600 nm), the turbidity-average diameter for suspensions of very small particles and the surface–volume-average diameter for suspensions of very large particles.

The particle size distribution and concentration of a colloidal dispersion can be determined by measuring its ultrasonic velocity and/or attenuation coefficient as a function of frequency and then using a suitable mathematical model to interpret the spectra. Ultrasonic spectroscopy can be used to analyze particle sizes between about 10 nm and 1000 μm, and is suitable for application to concentrated systems (often up to 50 wt%). This technique has considerable advantages over many alternative technologies because it can be applied to systems that are optically opaque without the need of any sample preparation.

1 INTRODUCTION

Ultrasonic spectroscopy utilizes measurements of the frequency dependence of the ultrasonic velocity and/or attenuation coefficient of colloidal dispersions to obtain information about the concentration and size distribution of colloidal particles. The velocity (c) at which an ultrasonic wave propagates through a particulate suspension, and the amount by which it is attenuated (α), are governed by interactions between the ultrasonic wave and the particles, e.g. transmission, reflection, absorption, and scattering. Ultrasonic attenuation spectroscopy (UAS) is more commonly used than ultrasonic velocity spectroscopy (UVS), although both methods can provide similar information. Ultrasonic spectroscopy has advantages over many existing particle-sizing technologies because it is non-destructive and non-invasive, is capable of rapid measurements and can be used to characterize systems which are concentrated and optically opaque. Ultrasonic spectroscopy is sensitive to particles with radius between about 10 nm and 1000 μm. The maximum particle concentration which can be analyzed varies between about 10 and 50 wt% depending on the nature of the system. On the other hand, the technique is unsuitable for analyzing dilute suspensions, i.e. particle concentrations below about 1 wt%. The other major limitations of the technique are that air bubbles can interfere with measurements and that a large amount of information about the thermophysical properties of the component phases are needed to interpret ultrasonic spectra.

There are two major steps in the determination of particle size using ultrasonic spectroscopy: (i) measurement of the ultrasonic velocity and/or attenuation spectra of the colloidal dispersion and (ii) interpretation of the resulting spectra using a suitable theory. To obtain accurate measurements it is necessary to carry out both steps carefully.

2 MEASUREMENT TECHNIQUES

Determination of the particle size distribution of a colloidal dispersion relies on being able to measure the frequency dependence of the ultrasonic velocity and/or attenuation coefficient.[1–3] The ultrasonic velocity is the distance the ultrasonic wave moves through the sample per unit time, whereas the attenuation coefficient is a measure of the decrease in the amplitude of the ultrasonic wave per unit distance traveled. The ultrasonic velocity can be determined by two different methods: (i) measuring the time, t taken for a pulse of ultrasound to travel a known distance, x: $c = x/t$, or (ii) measuring the wavelength of an ultrasonic wave, λ, at a known frequency, f: $c = \lambda f$. The attenuation coefficient is determined by measuring the reduction in amplitude of an ultrasonic wave which has traveled a known distance through a material (Equation 1):

$$\alpha = -\frac{1}{x} \ln \frac{A_x}{A_0} \tag{1}$$

where A_0 is the initial amplitude of the ultrasonic wave ($x = 0$), and A_x is the amplitude after it has traveled a distance x.

To cover a wide range of particle sizes it is necessary to measure the ultrasonic properties of a colloidal

Figure 1 Different types of signal used in the ultrasonic analysis of colloidal dispersions.

Figure 2 A typical ultrasonic spectrometer consists of a signal generator, a signal analyzer and a measurement cell.

dispersion over a wide range of frequencies.[2] Commercial ultrasonic particle-sizing instruments typically make measurements over the range 1 to 200 MHz, which enables them to analyze particles between about 10 nm and 1000 μm in radius. This range can be extended by using custom-built techniques to carry out measurements at higher or lower frequencies.[4–7]

The frequency dependence of the ultrasonic properties of colloidal dispersions can be determined using a number of different measurement principles.[4–8] The major difference between them is the form in which the ultrasonic signal is applied to the sample, i.e. continuous wave, tone-burst or pulse (Figure 1). Nevertheless, the experimental apparatus used in the different techniques is usually fairly similar, consisting of a signal generator, a signal analyzer and a measurement cell (Figure 2).

2.1 Continuous Wave Techniques

Ultrasonic spectrometers which utilize continuous waves are usually referred to as *interferometers*.[9] Interferometry of liquids can be carried out using two different types of experimental arrangement: fixed path length and variable path length (Figure 3).

Figure 3 An interferometer used to measure the frequency-dependent ultrasonic properties of liquids may be of the fixed path length or moveable path length type.

2.1.1 Fixed Path Length Devices

In a fixed path length (or resonator) device, the sample to be analyzed is placed in a thermostated measurement cell between two parallel piezoelectric ultrasonic transducers: a transmitter and a receiver. A signal generator produces an electrical sinusoidal wave of appropriate frequency and amplitude. This wave is applied to the transmitter where it is converted into a sinusoidal ultrasonic wave that propagates into the sample. The ultrasonic wave undergoes multiple reflections between the two transducers which results in the formation of a stationary wave. The signal detected by the receiving transducer is amplified and relayed to a signal analyzer. The amplitude of the received signal goes through a series of maxima and minima, due to constructive and destructive interference, when the frequency of the ultrasonic wave is varied. The ultrasonic velocity and attenuation coefficient are determined by analyzing the resulting amplitude versus frequency spectra.

To a first approximation the attenuation per cycle ($\alpha\lambda$) is given by Equation (2):

$$\alpha\lambda = \pi \frac{\Delta f_N}{f_N} \tag{2}$$

where f_N is the central frequency of a maxima and Δf_N is the width of the maxima at -3 dB, whilst the ultrasonic velocity is given by Equation (3):

$$c = 2d\Delta f \tag{3}$$

where d is the path length of the measurement cell and Δf is the frequency difference between the central frequencies of two successive maxima.

2.1.2 *Variable Path Length Devices*

In a variable path length device the sample to be analyzed is placed in a thermostated measurement cell which usually contains an ultrasonic transducer and a moveable reflector plate. A signal generator produces a sinusoidal electrical wave of the appropriate frequency and amplitude which is applied to the ultrasonic transducer where it is converted into a sinusoidal ultrasonic wave. The ultrasonic wave propagates into the sample and undergoes multiple reflections between the transducer and reflector plate which results in the formation of a standing wave. When the distance between the transducer and reflector plate is varied the amplitude of the signal received by the transducer goes through a series of maxima and minima because of constructive and destructive interference. The distance between successive maxima (Δd) is equal to half the ultrasonic wavelength of the sample, and so the ultrasonic velocity can be calculated: $c = f\lambda = 2f\Delta d$. The amplitudes of the maxima decrease as the distance between the reflector plate and transducer is increased because of attenuation by the sample. The attenuation coefficient is determined from Equation (1) by measuring the amplitude of the maxima as a function of the separation between the reflector plate and transducer.

Figure 4 The ultrasonic properties of a colloidal dispersion can be determined using pulsed techniques by (a) the through-transmission or (b) the pulse-echo methods.

2.2 Pulse Techniques

Ultrasonic spectrometers that utilize pulse techniques may be operated in a *pulse-echo* or *through-transmission* mode.[8,9] In the pulse-echo mode a single transducer is used to both transmit and receive the ultrasonic signal, whereas in the through-transmission mode separate transducers are used to transmit and receive the signal (Figure 4).

2.2.1 *Through-transmission Techniques*

The sample to be analyzed is placed in a thermostated measurement cell between two ultrasonic transducers: a transmitter and a receiver (Figure 4). The transmitting transducer produces a pulse of ultrasound which travels across the sample and is detected by the receiving transducer. The ultrasonic velocity and attenuation coefficient of the sample are determined by measuring the time-of-flight (Δt) and amplitude (A) of the ultrasonic pulse which has traveled across the sample. The ultrasonic velocity is equal to the length of the sample, d, divided by the time required to travel this distance: $c = d/\Delta t$. The attenuation coefficient is calculated by comparing the reduction in the amplitude of the pulse that has traveled through the sample with that of a pulse which has traveled through a calibration material: $\alpha_s = \alpha_c - \ln(A_s/A_c)/d$, where the subscripts c and s refer to the properties of the calibrant and sample, respectively. To obtain accurate attenuation measurements it is necessary to ensure that the measurement cell is well designed to minimize temperature fluctuations, reverberation of ultrasonic pulses in cell walls and transducers, diffraction effects and phase cancellation due to nonparallel walls.[8]

The frequency dependence of the ultrasonic properties of a sample can be obtained using two different approaches: (i) the Fourier Transform (FT) method, and (ii) the tone-burst method. For both approaches, a pair of ultrasonic transducers is used which is capable of generating ultrasonic energy over a wide range of frequencies. These *broad-band* transducers contain piezoelectric crystals whose oscillation is highly damped by attaching a backing material to the crystal.

In the FT method, a signal generator is used which is capable of producing a broad-band electrical pulse which contains a wide range of frequencies.[9–11] This pulse is applied to the transmitting transducer where it is converted into a broad-band ultrasonic pulse. After this pulse has traveled through the sample it is detected by the receiving transducer, and then digitized and stored. The frequency dependence of the magnitude and phase of the pulse are determined using a FT technique. The ultrasonic velocity is then determined from the phase, whilst the attenuation coefficient is determined from the magnitude. To cover the whole frequency range it is often necessary to use two or three pairs of broad-band transducers

with different central frequencies. Ultrasonic velocity and attenuation spectra are acquired much more rapidly using FT pulse techniques than continuous-wave techniques. This is because the whole of the frequency range is measured by propagating a pulse through the sample, rather than having to make measurements separately at each individual frequency.

In the tone-burst technique, a signal generator is used which is capable of generating tone-burst pulses over the required frequency range. A ''tone-burst'' is a single pulse which contains a number of cycles of ultrasound at a fixed frequency (Figure 1). A tone-burst pulse of a particular frequency is applied to the transmitter, and then the magnitude and phase of the tone-burst pulse that travels through the sample and is detected by the receiver are measured.[12] The ultrasonic attenuation coefficient is determined by measuring the amplitude of the received signal, whilst the ultrasonic velocity is determined by measuring the change in the phase of the received signal. An ultrasonic spectrum is acquired by repeating this process for a number of frequencies. Because measurements are carried out separately at each frequency, this approach is more time-consuming and laborious than the FT method.

2.2.2 Pulse-echo Techniques

The frequency-dependent ultrasonic properties of a sample are measured in a very similar fashion as in the through-transmission technique, except that a single transducer is used to both transmit and receive the ultrasonic pulses (Figure 4). The ultrasonic transducer generates a pulse of ultrasound which travels across the sample, is reflected from the back wall of the measurement cell, travels back through the sample, and is then detected by the same transducer. The velocity and attenuation coefficient are calculated in exactly the same manner as described for the through-transmission technique, expect that the pulse has now traveled a distance $2d$ rather than d.

To obtain accurate and reliable measurements it is important to take extreme care in designing and manufacturing measurement cells, for all types of ultrasonic technique. Some of the most important factors to consider are nonparallelism of surfaces, imperfect reflection at boundaries, reverberations in cell walls, temperature fluctuations and diffraction losses.[8]

3 PARTICLE-ULTRASONIC WAVE INTERACTIONS

A knowledge of the physical basis of the various forms of interaction between ultrasonic waves and particles is necessary to understand how ultrasound can be used to measure particle size.[1–3,8] The four most important types of interaction between an ultrasonic wave and a colloidal dispersion are listed below.

3.1 Intrinsic Absorption

Each of the individual component phases in a colloidal suspension absorbs ultrasound as a result of classical (viscous and thermal) and relaxation loss mechanisms. These losses are determined by the composition of the suspension, rather than by its microstructure. The magnitude of these losses can be calculated by measuring the ultrasonic absorption coefficients of the individual components.

3.2 Visco-inertial Dissipation Losses

In the presence of an ultrasonic wave a particle oscillates backwards and forwards because it has a different density to that of the surrounding liquid. This oscillation is damped by the viscosity of the surrounding liquid, which causes some of the ultrasonic energy to be converted to heat, and therefore leads to a reduction in the amplitude of the ultrasonic wave. The magnitude of these visco-inertial losses increases as the density difference between the droplet and surrounding liquid increases. Visco-inertial dissipation losses depend on the size of the droplets in a colloidal suspension.

3.3 Thermal Dissipation Losses

In the presence of an ultrasonic wave the temperature of a particle periodically increases and decreases relative to that of the surrounding liquid because of differences in the thermal properties of the continuous and disperse phases. The temperature gradient which arises at the particle surface causes a net flow of heat out of the droplet, which leads to a reduction in the amplitude of the ultrasonic wave, i.e. some of the energy initially stored in the ultrasonic wave is converted to heat. The magnitude of these losses is governed by the difference in thermal properties between the droplet and the surrounding liquid, e.g. thermal expansion coefficient, specific heat capacity and thermal conductivity. Thermal dissipation losses depend on the size of the droplets in a colloidal suspension.

3.4 Scattering Losses

The pulsation and oscillation of a particle in the presence of an ultrasonic wave causes the generation of secondary ultrasonic waves by the particle. Thus some of the ultrasonic energy associated with the incident wave is redirected into different directions, and an increase in

the attenuation coefficient may be detected. Scattering losses are usually negligible in the long wavelength limit ($r \ll \lambda$), but become dominant when the particle size is of the same order of magnitude as the ultrasonic wavelength. Scattering losses depend on the size of the droplets in a colloidal suspension.

To a first approximation, the overall attenuation coefficient of a colloidal suspension can be considered to be the sum of these various contributions (although in reality some of these mechanisms are coupled to each another). In most suspensions, one or two of the above mechanisms usually dominate the overall attenuation in a particular frequency range. At relatively low frequencies, the visco-inertial and thermal loss mechanisms usually dominate, but at higher frequencies the intrinsic absorption and scattering losses usually dominate.

4 ULTRASONIC SCATTERING THEORY

Once the ultrasonic velocity and/or attenuation spectra of an emulsion have been measured it is necessary to convert them into a particle size distribution using an appropriate theory. Theories are based on a mathematical treatment of the physical processes that occur when an ultrasonic wave propagates through an ensemble of particles suspended in a fluid.[1–3] One of the most comprehensive models (Equation 4) is based on multiple scattering theory:[13]

$$\left(\frac{K}{k_1}\right)^2 = 1 + \frac{4\pi N f(0)}{k_1^2} + \frac{4\pi^2 N^2}{k_1^4}(f^2(0) - f^2(\pi)) \quad (4)$$

where $f(0)$ and $f(\pi)$ are the *scattering amplitudes* of the individual droplets (Equations 5 and 6):

$$f(0) = \frac{1}{ik_1}\sum_{n=0}^{\infty}(2n+1)A_n \quad (5)$$

$$f(\pi) = \frac{1}{ik_1}\sum_{n=0}^{\infty}(-1)^n(2n+1)A_n \quad (6)$$

Here $K(=w/c_S + i\alpha_S)$ is the complex propagation constant, c_S is the ultrasonic velocity and α_S is the attenuation coefficient of the colloidal suspension. k_1 is the complex propagation constant of the continuous phase $(= w/c_1 + i\alpha_1)$, ϕ is the disperse phase volume fraction, $w(= 2\pi f)$ is the angular frequency f is the frequency, $i = (-1)^{1/2}$, and r is the droplet radius. The A_n terms are the *scattering coefficients* of the various types of waves scattered from the individual droplets, e.g. monopole (A_0), dipole (A_1), quadrupole (A_2) etc.

Approaches for calculating the scattering coefficients of both fluid and solid particles are available in the literature.[14,15] The most rigorous approach calculates the A_n terms by solving a series of 6×6 complex linear simultaneous equations at each value of n, although simpler analytical expressions are available in the long wavelength limit.[14,15] The values of the scattering coefficients depend on the relative thermophysical properties of the component phases, the ultrasonic frequency used and the size of the emulsion droplets. The terms containing ϕ in Equation (4) describe single scattering effects, whilst the terms containing ϕ^2 describe multiple scattering effects. Multiple scattering becomes increasingly important as the concentration of droplets in a colloidal suspension increases.

For a colloidal suspension containing polydisperse particles the above equation must be modified (Equation 7):

$$\left(\frac{K}{k_1}\right)^2 = 1 + \frac{4\pi}{k_1^2}\sum_j N_j f_j(0) + \frac{4\pi^2}{k_1^4}\sum_j N_j^2 \quad f_j^2(0) - f_j^2(\pi) \quad (7)$$

where the subscript j refers to the property with droplet size r_j. This equation can be used to relate the ultrasonic properties of a colloidal suspension (velocity and attenuation coefficient) to its thermophysical properties, composition (ϕ) and particle size distribution.

Recently, it has been shown that the above theory must be modified to take into account interactions due to overlap of viscous[16] and thermal waves[17] generated by the particles. These interactions cause large deviations between the classical multiple scattering theory and experimental measurements at low ultrasonic frequencies, small droplet sizes and high droplet concentrations.

5 INTERPRETATION OF ULTRASONIC SPECTRA

To determine the particle size distribution of a colloidal dispersion one usually measures its ultrasonic velocity and/or attenuation coefficient as a function of frequency. The particle size distribution is then determined by finding the droplet size distribution that gives the best fit between the predictions of the ultrasonic scattering theory and the experimental ultrasonic spectra.[1,2] There are two approaches to solving this inverse scattering problem: *model-independent* inversion and *model-dependent* inversion. In the model-dependent inversion method it is assumed that the particle size distribution follows some common form which can simply be modeled mathematically, e.g. log-normal (Equation 8).

$$P(r) = \frac{1}{x_g \ln \sigma_g \sqrt{2\pi}} \exp - \left(\frac{\ln^2 \sigma_g}{2}\right. \quad \exp\left(\frac{[\ln r - \ln x_g]^2}{2\ln^2 \sigma_g}\right. \quad (8)$$

where $P(r)$ is the probability of having a particle of radius r, x_g is the geometric mean of the radius and σ_g is the standard deviation of the geometric mean. The droplet size distribution can then be characterized by only two parameters: x_g and σ_g. The geometric mean and standard deviation which give the best agreement between the measured and predicted ultrasonic spectra are found by a least squares analysis. Most commercial ultrasonic instruments assume that the particle size distribution follows either a monomodal or bimodal log-normal distribution.

In the model-independent analysis no a priori assumption is made about the form of the particle size distribution. Although this method is scientifically more satisfactory, because many suspensions do not have particle size distributions which can be described by simple mathematical expressions, it is extremely time-consuming to compute. In addition, there are sometimes situations where a number of different particle size distributions give an equally good agreement between theory and experiment and it is not possible to decide which is correct.

6 APPLICATIONS

The ability of ultrasonic spectroscopy to determine the particle size distribution of colloidal suspensions has been demonstrated by many workers.[3,6,16,18–21] Fully automated particle sizing instruments which utilize ultrasonic spectroscopy are available commercially. These instruments are capable of measuring both the disperse phase volume fraction and particle size distribution of colloidal suspensions in a few minutes. For certain systems, these instruments are capable of characterizing suspensions containing high particle concentrations (sometimes as high as 60%).

The attenuation spectra of a series of corn oil-in-water emulsions with different disperse phase volume fractions (1–50 vol%) are shown in Figure 5. The particle size distribution and droplet concentration measured by the ultrasonic technique are tabulated in Table 1. There is excellent agreement between the measured and actual volume fractions of the emulsions up to the highest droplet concentration. In addition, the mean particle diameter is relatively insensitive to droplet concentration, indicating that the ultrasonic technique is capable of analyzing this system over a wide range of concentrations without any sample preparation. Nevertheless, it should be noted that in systems where thermal or viscous overlap effects become important there may be quite large disagreements between the experimental data and the theories used to interpret them.[16,17]

Figure 5 Ultrasonic attenuation spectra of corn oil-in-water emulsions containing different droplet concentrations. The particle size distribution and disperse phase volume fraction are determined by finding the values which give the best-fit between the measurements and ultrasonic scattering theory.

Table 1 Disperse phase volume fraction (ϕ), geometric mean (x_g) and standard deviation of the geometric mean (σ) of various corn oil-in-water emulsions determined by finding the best fit between ultrasonic scattering theory and the experimental measurements shown in Figure 5

Actual ϕ	Measured ϕ	x_g (μm)	σ
50	47.9	1.32	2.50
40	37.9	1.17	2.24
30	30.1	1.20	2.07
20	20.6	1.18	1.93
10	10.5	1.14	1.85
5	5.5	1.16	1.74
1	1.5	1.30	1.14

7 PERSPECTIVE AND FUTURE DEVELOPMENTS

The ability of ultrasonic spectroscopy to characterize colloidal suspensions which are concentrated and optically opaque without the need for any form of sample preparation is extremely important for many applications. There are few other particle sizing technologies which are capable of analyzing this type of system and therefore it seems likely that the ultrasonic technique will find increasing applications in the future. One of the areas where the technique is most likely to be used is for the on-line determination of particle size distributions of colloidal suspensions during processing. The ultrasonic technique could be used to monitor the efficiency of a processing operation in real time that could lead to a major improvement in the manufacture of many colloidal-based materials, e.g. foods, pharmaceuticals, petrochemicals, agrochemicals and cosmetics.

Despite its many advantages over alternative technologies there are a number of technical issues that need to be addressed before the technique finds more widespread use:

1. The classical multiple scattering theory used to interpret ultrasonic measurements gives excellent agreement with experimental data for semi-dilute emulsions containing noninteracting droplets. Nevertheless, it needs to be extended so that it can be applied to more concentrated emulsions and to take into account the effects of droplet flocculation.
2. The interpretation of ultrasonic measurements requires knowledge of a number of the thermophysical properties of the disperse and continuous phases, which are often not readily available in the literature or are difficult to measure. It is therefore important to develop a database of the relevant thermophysical properties for the materials commonly found in colloidal suspensions.
3. The presence of small gas bubbles can obscure the signal from colloidal particles because of their ability to strongly scatter ultrasound. Strategies for overcoming this problem need to be developed, e.g. degassing the sample or making measurements at frequencies where the gas bubbles do not scatter significantly.

Velocimetry in particle size analysis encompasses the range of issues and methods used to measure particle velocities consistent with particle size measurement systems. Particle size may be measured simultaneously or consecutively with the velocity measurements described in this article. This article will present some issues that should be considered in selection of a velocity measurement technique. Three examples of commonly used particle velocity methods will be discussed as illustrations of possible approaches. For each of these examples, a brief discussion of advantages and limitations of the methods will also be presented.

1 INTRODUCTION

A wide variety of physical situations call for measurement of particle or droplet velocities. In many cases, these measurements accompany size measurements, but in some cases particle size measurements are not necessary. This section will focus primarily on the velocity measurements, with some mention of systems which can acquire both size and velocity measurements. The intent is to introduce some of the more common methods in use for measurement of particle and droplet velocities. It is likely that some useful techniques will not be included, but this article may serve as a useful introduction to some of the techniques. In many cases, the measurement methods described are available as partial or complete systems from commercial vendors.

Measurement of particle or droplet velocity can be a challenging task both in acquiring data with appropriate characteristics and in interpreting the measurements so that accurate and appropriate conclusions can be drawn from the experiment. This article will outline some of the attributes of the particles (distributed phase) and the background fluid or continuous phase that should be considered in making measurements of particle or droplet velocities. I will also describe some of the most common current methods used to acquire such measurements. While some example applications will be included, inevitably many areas of interest will not be fully explored. Hopefully, readers will be able to use this introduction to aid in thinking about such measurements, and will feel capable of searching for applications in the open literature that are directly applicable to their areas of interest.

In the context of velocity measurements for particles and droplets, ''particles'' may strictly include a wide range of materials, with the common understanding that a ''particle'' is a solid or apparently solid-phase material suspended in a different phase (gas or liquid) field. Solid particles may exist in solid suspensions, but this combination will not be explicitly discussed in this article. Droplet velocity measurements, however, will be included. A ''droplet'' is considered to be a small amount of a liquid-phase substance suspended in a different liquid or a gas phase. Many of the methods and considerations in this article also apply for bubbles–gas phase suspended in liquid phase. In subsequent parts of this section, ''particle'' velocity measurements will refer to measurements of solid particles, droplets, or bubbles, unless otherwise specified.

Since particle or droplet motion usually involves a continuous phase different from the particle or droplet phase, two-phase or multiphase flow considerations are important in developing measurement systems for these types

Encyclopedia of Analytical Chemistry

of flows.[1] One of the most important considerations in a multiphase flow is the lack of continuity for the distributed phase (droplet or particle) of the flow. Whether particles or droplets, as discrete entities, they have a distinguishable, Lagrangian character. In many cases, this means that the appearance of particles or droplets at a specific place and time in a flow (aside from any vector or scalar characteristics) seems to be a random event with some statistical character. In contrast, the continuous phase (usually liquid or gas) is almost always present at any location at any time in the flow field (except when displaced by particle or droplet). While some measured characteristics of the continuous phase may appear to be random (like instantaneous velocity in a turbulent field) the presence of a velocity value is not. The discontinuous sampling for particles and droplets presents some difficulties in measurement and interpretation of measurements, which will be discussed in later sections of this article.

The type, quantity, and quality of velocity information sought for particles or droplets will vary with the application and the flow of interest. One useful initial distinction is whether the particle velocity field is of interest in its own right, or is intended to be a marker for another flow field, typically the continuous phase flow field. While particle measurement methods may be similar for these two, the type of information sought may differ considerably.

The kind of information sought about a particle or droplet velocity may include the velocity magnitude, direction, and some marker of time and space to indicate where and when the velocity sample was acquired. In many cases, the detailed spatial and temporal markers are not retained; instead, spatial information is recorded from the known sample volume location or the location of the particle velocity sampling, and temporal marking may be eliminated in favor of some statistical temporal moments (like mean velocity and root mean square (RMS) velocity). Since measurement methods and details may change depending on which of these quantities is needed, initial selection of the type of information sought can be an important step in developing or selecting a measurement system.

While the range of possible measurement methods is broad, the most commonly used particle velocity measurement techniques seem to fall into three major categories: optical LIDAR (Light Detection and Ranging) type methods which rely on Doppler shift of laser light; laser Doppler velocimetry (LDV) systems which also rely on Doppler effects but in a different configuration; and direct particle imaging systems. These three types of measurements, and some variations, will be emphasized throughout this article.

2 CLASSIFICATION OF FLOW TYPES

2.1 Characteristics of Particle Flows for Velocity Measurements

In order to select velocity measurement methods that are well suited to the situation of interest, it may be useful to identify and describe some relevant parameters of the particles or droplets and some parameters of the flow field. In this section, some relevant particle parameters will be identified and typical ranges described. In the following section, relevant parameters of the continuous phase or mean flow field will be described.

Some particle characteristics that impact selection and use of velocity measurement methods are shown in Table 1, and will be discussed below. The range of ''typical'' values shown in Table 1 is primarily for illustration. It is quite likely that successful particle velocity measurements can be made beyond the cited range of each characteristic, but a range is cited to give readers an idea of the range encountered in experiments.

Particle size is one of the most important of the particle characteristics that affect what kind of velocity measurement could be made and the quality of the

Table 1 Some relevant particle characteristics

Particle characteristic	''Typical'' range of values
Size (diameter)	$10\,\text{nm} < d_p < 1.0\,\text{mm}$
Number density (no. of particles/volume of distributed phase)	$1\,\text{cm}^{-3} < n < 10\,000\,\text{cm}^{-3}$ (or more)
Material density (mass of particle/particle volume)	$1.2\,\text{kg m}^{-3} < \rho_m < 1000\,\text{kg m}^{-3}$
Shape (aspect ratios, e.g. d_1/d_2, d_1/d_3)	Spherical ($d_1 = d_2 = d_3$) to $d_1/d_2 \gg 1$ or $d_1/d_3 \gg 1$
Complex index of refraction ($n = m + ik$)	Nonabsorbing, near vacuum ($n = 1 + i0$) to highly absorbing ($k > 0$), high density ($m > 1$)
Steady or transient particle velocities	$1\,\mu\text{s} < \tau < 10\,\text{s}$ (or more)
Surface finish	No clear definition, in this context
Chemical characteristics (toxicity, reactivity, ...)	Nontoxic, nonreactive ... to ... quite toxic and/or reactive
Phase or chemical mutability (vaporization of droplets, reaction for liquid $TiCl_4$ with water vapor $\Rightarrow TiO_2$, ...)	Depends on physical constants (vapor pressure), particle chemistry, and environment (T, P, composition)

resulting measurement. The size range of particles whose velocity can be measured is relatively large. In particular, if the velocity measurement does not require a parallel size measurement, quite small particle sizes can have velocities measured. As will be discussed in the following sections, particle size (along with some other parameters) affects the detectability of the particle, its ability to accelerate and decelerate in concert with the continuous phase, and even whether and how particles will distribute themselves throughout a flow. Some of these topics will be discussed in later sections of this article; for others, readers will be referred to resources addressing these issues.

Perhaps the second most limiting characteristic for particle velocity measurement is the *number density* of particles in the region of interest. In many applications, identifying the velocity of a single particle, not the average velocity of an aggregate of particles, is the goal. To the extent that a single particle cannot be ''isolated'' mechanically or optically, it may be difficult to tag a particular particle with a specific velocity value. In other flows, an average velocity for an aggregate (spatial average) of particles may be sought; if the number density is too low, some methods designed for this type of measurement may not work properly. Most of the particle velocity techniques that will be discussed have ranges of particle number density in which they will work best. Outside of these ranges, the results of the method may not prove satisfactory.

Particle material density is related to index of refraction of the particle as well as its ability (or lack thereof) to be neutrally buoyant in the distributed phase. For marker particles, an expectation is that particles follow the continuous phase to some limit, which usually includes minimum and maximum velocities and acceleration. For example, to follow low velocity continuous-phase flows, particles need to be nearly neutrally buoyant in the fluid, or else they will have gravitationally induced velocities unrelated to the continuous phase velocity. Even in high-velocity flows, particles and droplets may have slip velocities relative to the continuous phase for transient flows.[2]

Particle shape affects the way in which a particle can or will follow a continuous-phase flow, as well as the way in which a particle will scatter light. As mentioned above, many of the particle velocity techniques currently in use depend on light scattering from particles. Nonspherical particles may scatter adequately for some velocity measurements, but present significant difficulties when accompanying sizing methods are used. Further, since many size and velocity methods, like phase Doppler interferometry (PDI) expect spherical particles, the velocities associated with nonspherical particles may be discarded, leading to shape-biased velocity statistics. Identifying scattered light signatures, if that is important, from randomly oriented nonspherical particles is likely to be very difficult.

The particle *complex index of refraction* (and its relation to the continuous-phase index of refraction) combines the refractive effect of change of index of refraction at the particle–fluid interface and the absorption characteristics of the particle. In general, index of refraction for a particle is temperature dependent, and for many materials is only known approximately. Since many particle velocity measurement methods are optically based, this optical parameter is frequently an important parameter affecting scattered signal strength and system signal-to-noise.

Surface finish and the *chemical characteristics* of the particles are also characteristics that can affect choice and implementation of methods. Surface finish is presumably an issue only for solid particles (or perhaps very large droplets and bubbles where the local surface tension and radius of curvature of the interface are not sufficient to produce a ''smooth'' interface). Chemical characteristics may include mostly practical considerations for material handling and disposal, although some characteristics (like fluorescence) can be used as part of the measurement method.

Mutability of the particle refers to whether the particle composition or phase will change under the conditions of the experiment. In some cases, this feature may be a disadvantage, for example when oil droplets are used as markers for a heated gas flow, and the markers vaporize leaving no particles to detect in the flow. In other cases, this mutability can be used to advantage. For example, a liquid like $TiCl_4$ could be atomized into a fine spray in a gas flow with some water vapor in the gas. A chemical reaction of the $TiCl_4$ with the water vapor produces TiO_2 powder and HCl vapor. The TiO_2 provides small markers for the flow; dispersing the $TiCl_4$ as a liquid spray may provide better particle size control than dispersing the TiO_2 powder itself.

In summary, in order to focus on a set of methods likely to be successful for measuring the velocity of a class of particles or droplets, identifying the range of expected particle characteristics is an important first step. When particles are intentionally seeded into a flow, the selection of seed may be revisited once a measurement method has been selected to optimize the combination of particle and method. For naturally occurring particles, careful characterization of the particle characteristics can help make a successful measurement with a minimum of trial-and-error.

2.2 Characteristics of Continuous Phase for Particle Velocity Measurements

As was the case for particle characteristics, certain characteristics of the continuous phase have a

Table 2 Some relevant flow (continuous phase) characteristics

Flow characteristic	"Typical" range of values
Size of flow field of interest ($l \times w \times h$)	1 mm × 1 mm × 1 mm to 10 m × 10 m × 10 m
Access (locations, characteristics of access locations)	Limited (e.g. single location) to everywhere in flow field
Temporal variation of velocity and scale of variation	Steady laminar to unsteady (mean) turbulent
Spatial variation of flow field velocity	Uniform or not
Repeatable?	Yes or no
Complex index of refraction ($n = m + ik$)	Nonabsorbing, near vacuum ($n = 1 + i0$) to highly absorbing ($k > 0$), high density ($m > 1$)
Fluid density	$1.2\,\mathrm{kg\,m^{-3}} < \rho_f < 1000\,\mathrm{kg\,m^{-3}}$
Chemical characteristics	Nontoxic, nonreactive ... to ... quite toxic and/or reactive

significant impact on the success of particle measurement. Table 2 outlines some of the more common flow parameters that affect the choice of particle velocity measurement methods and the measurements themselves.

Many of the general features of a particular experiment are embodied in the description of the continuous phase flow field characteristics. These features include the size of the region of interest, access to the region, and whether the general flow is expected to be steady or transient. Taken together, these features start to suggest whether some sort of instantaneous "snapshot" of the particle velocities everywhere in the flow field is needed, or sampling particle velocities at one location over time is sufficient, or if something in between is needed.

In Table 2, the *size of the flow field* represents the total spatial region of interest. For imaging systems, this may indicate the size of the object field that needs to be imaged. *Access*, in Table 2, refers to the range of locations in the flow field where a sample of the continuous and distributed phase velocity might be available. As most current particle velocity measurement systems are optical, *access* refers primarily to optical access. For some flows, the flow may be accessed or sampled at only a few locations, with a limited "field of view". Other experiments may have fewer limitations, perhaps allowing optical access to a large portion of the flow field for much of the time of interest. These access constraints may be important in selecting and applying a velocity measurement system because the systems themselves require different levels of access.

Temporal variation of velocity and the *scale and frequency of variation* are indications of the flow characteristics of the continuous phase. Many flows have an unsteady or even turbulent character. Depending on the magnitude and frequency of the behavior, for many of these flows, a statistical representation of particle velocity may be most useful. Typical flow statistics of interest may include a mean velocity, a RMS velocity, and perhaps higher moments of the velocity. Flows may exhibit very little variation from a steady mean velocity or slowly varying mean velocity (i.e. small magnitude or very low-frequency variations), indicating a laminar-type flow. Alternatively, the flow may be a transient turbulent flow with time-varying statistics (mean, RMS, moments). Estimating the temporal characteristic of the flow is quite useful in assessing what kind of measurement, what data rate, and what resulting statistics are desired. Flow repeatability is related to this transient character, since this characteristic, when present, makes a repeated measurement on different realizations of the flow possible. A nonrepeatable flow would not permit such a data combination without significant degradation to the resulting data set.

Spatial variation of the velocity is the estimate of whether data sampled in one region of the flow are representative of that region alone, or of some broader range of locations. In parallel with temporal variations, spatial variations of flow velocity can be very small to quite large, responding to the flow geometry as well as to the overall flow type and structure.

The *complex index of refraction* and *fluid density* are of interest on their own, but are even more important when compared with the distributed phase of particles or droplets. Similar particle and continuous phase densities may make particles more likely to follow the flow (neutrally buoyant), while similar indices of refraction may make particles more difficult to identify because of the refractive characteristics for optical measurement systems. While most particle velocity measurement methods do not require exact knowledge of the particle or fluid (continuous phase) index of refraction, signal levels are affected by the difference in index between the particle and fluid.

As for the particles, *chemical characteristics* may be of interest in the measurement itself, or may be part of the measurement system (as for fluorescence) or may be issues to handle for chemical handling and disposal.

3 FUNDAMENTAL CHARACTERISTICS OF MEASUREMENT METHODS

3.1 Particle Characteristics Useful for Velocity Measurements

Particle velocity measurements are based on a variety of measurable quantities. Currently, the most common particle velocity measurement methods employ optical or ultrasonic scattering of incident waves. Typically, a portion of a signal, scattered by the particle field, is collected and analyzed to estimate particle velocity. Of the many techniques available, optical techniques seem to be most widely used, and will be emphasized throughout this discussion. The methods used in extracting the information from the scattered or unscattered signal distinguish one particle velocity method from another. As a result of the information extraction and analysis methods, the resulting measurements acquire specific characteristics and limitations.

In some situations, it is useful to use some other particle-related signal source besides scattered light. One type of particle-related signal source, which has been used successfully, is particle or droplet fluorescence, in which a particle absorbs light of a certain wavelength and immediately emits light of a different, usually longer wavelength. Since the particle acts as a virtual light source for the emission wavelength, the variation of the signal with particle size, number density, and other characteristics is a little different than for signals from light scattering. Nevertheless since scattering is the most common approach in use, we will look at light scattering in some detail.

Among many different specific particle features which are usable for velocity measurement, there are two that seem to be the most widely used. One of these is the particle location, provided by viewing or recording an image of the particle at a sequence of well-known times. The second quite different particle characteristic that is frequently used is the frequency of light scattered from a particle of interest. A common requirement for either of these optical methods is the ability to collect a sufficient amount of light from a particle at some time and location. Among the issues of interest in enabling collection to occur are the object signal level (actually signal-to-noise) of the particle, and the resolution of the illumination and imaging system. Issues affecting the signal level will be described briefly in this section, while resolution issues will be presented in the following section.

For optical particle velocity methods, the intensity of light scattered from a particle is usually calculated from Lorenz–Mie theory (LMT) for scattering of light from spherical particles. Van de Hulst[3] presents the general LMT equations as well as some special cases (e.g. $d < \lambda$, $d = \lambda$, or $d > \lambda$, where d is the particle diameter), although all examples assume uniform illumination. Other work[4] has extended LMT to include nonuniform illumination, as might occur for illumination by a Gaussian cross-section intensity laser beam. To illustrate the effect of the important parameters in particle light scattering, the basic LMT will be briefly outlined. A more complete presentation is given in Van de Hulst.[3] The formulation used by Van de Hulst for a spherical particle gives the description of scattering as a generalized solution to a wave equation as shown in Equations (1) and (2).

$$\Delta\psi + k^2 m^2 \psi = 0 \tag{1}$$

$$\psi_{\ln} = \left\{ \begin{matrix} \cos l\phi \\ \sin l\phi \end{matrix} \right\} P_n^l(\cos\theta) z_n(mkr) \tag{2}$$

where $n \geq l \geq 0$, $k = 2\pi/\lambda$, r is the radial distance from the center of the particle, z is the propagation direction of the beam, $P_n^l(\cos\theta)$ is a Legendre polynomial, and $z_n(mkr)$ is a spherical Bessel function. The incident light is assumed to be linearly polarized.

The incident beams can be written (for the two solutions to the wave equation) as in Equations (3) and (4):

$$u = e^{iwt} \cos\phi \sum_{n=1}^{\infty} (-i)^n \frac{2n+1}{n(n+1)} P_n^l(\cos\theta) j_n(kr) \tag{3}$$

$$v = e^{iwt} \sin\phi \sum_{n=1}^{\infty} (-i)^n \frac{2n+1}{n(n+1)} P_n^l(\cos\theta) j_n(kr) \tag{4}$$

The field outside a sphere resulting from scattering from the sphere and the incident wave, is given by Equations (5) and (6)

$$u = e^{iwt} \cos\phi \sum -a_n (-i)^n \frac{2n+1}{n(n+1)} P_n^l(\cos\theta) h_n^{(2)}(kr) \tag{5}$$

$$v = e^{iwt} \sin\phi \sum -b_n (-i)^n \frac{2n+1}{n(n+1)} P_n^l(\cos\theta) h_n^{(2)}(kr) \tag{6}$$

where $h_n^{(2)}(kr)$ is a spherical Bessel function of the second kind.

The coefficients a_n and b_n can be determined using Riccati–Bessel functions as in Equations (7–9)

$$\begin{aligned} \psi_n(z) &= z j_n(z) \\ \chi_n(z) &= -z n_n(z) \\ \zeta_n(z) &= z h_n^{(2)}(z) \end{aligned} \tag{7}$$

$$a_n = \frac{\psi_n'(y)\psi_n(x) - m\psi_n(y)\psi_n'(x)}{\psi_n'(y)\zeta_n(x) - m\psi_n(y)\zeta_n'(x)} \tag{8}$$

$$b_n = \frac{m\psi_n'(y)\psi_n(x) - \psi_n(y)\psi_n'(x)}{m\psi_n'(y)\zeta_n(x) - \psi_n(y)\zeta_n'(x)} \tag{9}$$

where $x = ka = 2\pi a/\lambda$ and $y = mka$.

For a specific index of refraction particle, calculations of the relative scattered intensity as a function of particle size and scattering direction can be calculated from

Figure 1 Calculated Mie scatter for 0.5, 2, and 10 μm spherical particles ($m = 1.5 + 0i$) as a function of collection angle. The calculation uses the methods of Bohren and Huffman.[5]

Figure 2 Calculated Mie scatter for forward scatter (collection from 0 to 4°) and back scatter (collection from 176 to 180°) as a function of particle size. The calculation uses the methods of Bohren and Huffman.[5]

Equations (5–9). Sample results for such calculations are shown in Figures 1 and 2 for several particle sizes at a range of scattering angles. Figure 1 shows the variation of scattered intensity for uniformly illuminated 0.5-μm, 2-μm, and 10-μm particles, as a function of collection angle, calculated using the method described by Bohren and Huffman.[5] Even with the apparently small difference in size between 0.5 μm and 2 μm, the scattered intensity values are very different at most of the scattering angles shown. At the forward scatter collection direction (0°) the 10-μm particle shows over 10^2 greater scattering intensity than the 2-μm particle, and about 10^4 greater than the 0.5-μm particle scattering intensity at this collection angle. In this calculation, individual angles are calculated separately; actual collected light signals may differ somewhat from the scattered intensities shown because the optical collection system collects over a finite solid angle and will integrate over some of the irregularities of the single particle scattering curves. Figure 2 shows the variation of scattered light intensity with particle size for "forward scatter" and "back scatter" collection angles. For these calculations, scattered intensity was integrated over 4° about 178° (176° to 180°) for forward scatter, and over 4° about 2° (0° to 4°) for back scatter. The changes in signal level with particle size for either collection configuration are significant. In addition, the difference between forward and back scatter for a given particle size is evident. The calculations shown neglect some real behavior likely to be present in scattering situations, like nonuniform illumination, but they give some order-of-magnitude estimates for the impact of particle size and collection angle on signal strength.

Experimental measurements of particle scattering efficiency for different particles are available.[6,7] An example of these measurements is shown in Figures 3 and 4. Figure 3 shows the minimum detectable particle diameter (defined as allowing >70% of the particles to be detected on film) in air as a function of the f number of the collection lens and the laser power used. Figure 4 shows the same basic results in a water flow. These measurements have focused on optical arrangements typical of LDV systems or particle imaging systems.[7] In general, the experimental results are consistent with the scattered light calculations for dilute particle systems in which single-particle scatter of nearly spherical particles dominates.

Figure 3 Experimental minimum detectable particle diameter in air as a function of collection system f number and illuminating laser power. (Figure from Adrian and Yao[7] and reproduced by permission of the Optical Society of America.)

Figure 4 Experimental minimum detectable particle diameter in water as a function of collection system f number and illuminating laser power. (Figure from Adrian and Yao[7] and reproduced by permission of the Optical Society of America.)

For some dense particle fields, the single particle scatter predicted by Van de Hulst and others is more the exception than the rule. In these systems the actual collected signal may differ considerably from the predictions due to multiple scattering of photons from not one, but several particles. There does not seem to be the same kind of detailed analysis of the high number density particle fields as for the low number density fields. The issue has been, and continues to be one of great interest because so many practical particle or droplet fields are, in fact, quite dense. These past studies include analysis of dense fields themselves,[8] their effect on common measurement methods,[9] and possible resulting biases in measurements made in these kinds of fields.[10] More specific comments on the difficulties inherent in high number density particle fields will be mentioned in the discussions of detailed techniques. The problems associated with these high particle number density fields vary somewhat depending on the choice of measurement method.

The results of either calculations or measurement for single particle scattering provide guidance in selecting parameters for experiments. Scattering from large particles is clearly much stronger than from smaller particles; "forward" scatter directions result in much higher signal levels than for other scattering directions. In general, diffraction is not included in these calculations, and for forward scatter, diffraction may dominate the refraction and reflection signals modeled by the LMT calculations.

Depending on the measurement scheme selected, different specific attributes of the scattered particle signal may be sought. Understanding of the general behavior of particle scattering may be a great help in designing a successful experimental method. Under some circumstances, calculating the relative or absolute scattering in a given direction for a particle size range may be useful, using the equations given by Van de Hulst or some more recent work suggesting how to speed up the recursive calculations involved.[11] Some of this more recent work has also included nonuniform illumination (i.e. Gaussian beam profiles – a common occurrence in laser illumination of particles).[12,13]

3.2 Temporal and Spatial Resolution Requirements and Limitations

A second major issue for most particle velocity measurement systems is accommodating the temporal and spatial resolution required to accurately evaluate the physical system. The range of spatial and temporal resolutions available from measurements is closely tied to the ability to capture a scattered signal with adequate signal-to-noise in a limited time over a prescribed volume. Currently, hardware limitations have a significant effect on the range of temporal and spatial resolutions achievable. Hardware and data "bandwidth" limitations often cause spatial and temporal resolution capabilities to be intertwined, not independent of one another.

There are many common choices for spatial and temporal resolution. For example:

- low spatial and low temporal resolution – as for measurement of a steady homogeneous particle field; particle velocity measurement might be spatially averaged over a volume of 10 m × 10 m × 10 m with a temporal resolution of 1 s (update rate);
- moderate spatial resolution, low temporal resolution – as for the measurement of a steady particle flow with spatial values desired every 1 cm in a 1 m × 2 m × 10 m volume; temporal resolution might be about 1 s;
- high spatial and temporal resolution – as for measurement of an unsteady, inhomogeneous flow with spatial values desired every 1 mm in a 100 mm × 100 mm × 100 mm volume; time constant of the flow is expected to be about 50 μs, requiring data rates of 40 kHz (2 × 20 kHz to satisfy Nyquist criterion) or greater.

Table 3 Examples of temporal and spatial resolution capabilities for typical particle velocity measurement systems

Technique	Spatial sample volume size range	Temporal sample range
Doppler shift (LIDAR-type) methods	10 cm × 10 cm × 300 m (typ)	10 ns "snapshot" at 10 Hz or more (laser pulse rate) update rate
LDV	300 μm × 300 μm × 1 mm	10 μs at 200 kHz (signal processing rate) update rate
Direct imaging methods	1 mm × 1 mm × 1 mm	10 ns "snapshot" at 10 Hz or more (laser pulse rate or camera framing rate) update rate

Each of these measurements presents quite different spatial and temporal resolution requirements and will result in different selection of experimental parameters, if not in different experimental procedures altogether. Within any technique, a range of capabilities is possible with different experimental strategies or hardware. For the techniques most commonly used in particle velocity measurements, typical ranges are shown in Table 3.

In this table, "Spatial sample volume size" is intended to indicate the spatial volume over which measured particle values are averaged, producing one velocity vector for each specified volume of particles regardless of how many particles may be present in the volume. Clearly other values, both larger and smaller are possible with different selection of experimental parameters. The major point of Table 3 is to illustrate the differences among three common particle velocity measurement techniques in terms of spatial and temporal velocity value resolution. For example, a LDV (sometimes known as a laser Doppler anemometer or LDA) system usually has a relatively small sample volume and has the ability to sample particle velocities within that volume at quite high rates. However, LDV or LDA systems have no innate capability of providing multiple simultaneous samples at many different locations – although multiple systems can provide multiple sample volumes. In contrast, some direct imaging systems can sample at a great many locations within a flow simultaneously (via a two-dimensional image), but due to the difficulties of rapid, pulsed, illumination and rapid storage and transfer of images, most are not able to provide a temporal succession of images at a rate anywhere close to the sampling rate of the LDV system. Depending on the flow and type of information sought, either or both of these systems may produce useful information, but the choice of measurement system needs to be matched to the kind of information sought, bearing in mind the current limitations of each of the methods.

It should be noted that these methods need not be used exclusively, but can be used in complimentary ways. For example, a direct imaging method might be used to provide large-scale spatial data from a flow field and to provide data on spatial flow patterns in the flow field. An LDV system could be used to probe locations of particular interest to provide a temporal record of velocity values at a number of discrete locations.

New methods of particle velocity measurement are constantly being developed to provide capabilities not available with current systems or to adapt some current systems to new applications. For example, a recent combination of full-field particle imaging with Doppler shift measurement produces "global" Doppler velocimetry[14] which looks like a high spatial resolution version of the single detector LIDAR type systems.

One unmentioned, to this point, but quite important issue in comparing different approaches to particle velocity measurement is the inherent dynamic range of velocity which can be measured, the accuracy with which a velocity can be measured, and the uncertainty in the measurement. These attributes are also significant in selecting an approach for velocity measurement, but the actual values will vary with details of the application, including hardware and software used. Some discussion of these issues, and the ranges that may be possible, will appear in the sections specifically describing the most common implementations of the approaches outlined here.

3.3 Coupling Velocity and Particle Size Measurements

Throughout this discussion of particle velocity measurements, the possibility of obtaining simultaneous particle size and velocity measurements has been ignored. There are methods that combine one of the presented velocity measurement methods with a particle size measurement to produce simultaneous size and velocity measurement, and consequently size–velocity correlations. By far the most common commercial method for this kind of measurement is the phase Doppler method, here generically called PDI.[15,16] This method relies on an LDV type system for velocity measurement and a phase-shift method for size analysis. Since particle size measurements are covered in a different entry in this volume, they will not be presented here. The velocity measurement portion of these systems is very similar to the LDV systems used in velocity-only measurements, so discussion of velocity-only measurements may be extended to the velocity part of PDI size and velocity measurements fairly easily.

A second set of methods for combined size and velocity measurements involves some of the direct imaging methods discussed below, combined with particle size evaluation from the images. As for the PDI systems, the velocity portion of these measurements is similar to direct imaging, velocity-only measurements. A major exception to this similarity is the requirement for accurate particle image sizing. For velocity and sizing, the imaging system must produce accurately sized particle images. As this is not strictly necessary for velocity-only measurements, in most cases this presents a much stricter requirement on the imaging and recording system than velocity-only systems require. These additional requirements will be discussed in the portion of this volume that focuses on particle sizing.

3.4 Biases and Uncertainties in Particle Velocity Measurements

Any measurement is likely to have some bias and uncertainty. For the methods described in this short overview, many of these biases have been studied extensively. Rather than repeat those evaluations, readers will be referred to reference works on the subject.[2,17]

In general, biases for particle velocity measurement arise for a variety of reasons. The most notable biases are due to the limited ability of a sample of particle velocities to represent the entire ensemble of particle velocities in the flow, and the instrument characteristics that do not sample all particle sizes and velocities "fairly". For example, in many flows particles exhibit a distribution of velocity magnitudes and directions. For a sample of particles streaming through a fixed control volume over a fixed period of time, the probability of high-velocity particles passing through the volume is higher than the probability of low-velocity particles. The resulting ensemble of particle velocities may not accurately represent the true distribution of velocities as high-velocity particles may be overrepresented. This particular "velocity bias" is well known in the LDV field and some corrections for the bias have been suggested.[2,17]

Because of the complexity of obtaining any particle velocity values in some situations, it is tempting to assign any values obtained as representative of the entire particle field. Any method known to the author has some bias associated with it, whether that bias can be quantified and "corrected" or not. Users should try to recognize the range of biases likely in any application and, if it is not possible to reduce or correct for these characteristics, acknowledge their presence and likely influence on the resulting data and conclusions.

For approaches outlined in this article which rely on the ability to detect Doppler frequency shift in a light beam for measurement, the major difficulties arise in the separation of the shifted light frequency from the unshifted light frequency, and the association of the intensity of shifted light at a shift frequency with particle velocity. This topic has been presented in several papers discussing LIDAR applications and similar Doppler shift measurements.[18]

For LDV systems, measurement bias has also been a consideration almost since the technique was developed. While corrections for some of the known biases inherent in the method have been developed,[19] for other biases (like a nonrepresentative sample), no real correction is available without significant assumptions about the overall character of the particle and continuous phase flow.

Direct imaging approaches have also been examined in some cases for measurement biases, and a series of guidelines have been suggested to minimize the impact of some of these biases.[20,21] Even so, because of the complexity of the experimental technique, direct imaging approaches remain susceptible to biases in the measurement, which are not always recognized.

4 APPLICATIONS OF MEASUREMENT APPROACHES

4.1 Frequency Shift (Doppler) Methods

Frequency shift or Doppler shift methods rely on the frequency shift of light scattered from a particle for measurement of particle velocity. Successful implementation implies a well-characterized linewidth for the incident light, and some knowledge of the scattering characteristics of the particle or particles. Two implementations of Doppler shift methods will be outlined in this section. The first of these is a LIDAR system designed for measurement of atmospheric velocities by sampling particle (aerosol) or molecular velocities. The second implementation of a Doppler shift approach is LDV. This method is commonly used to measure particle or droplet velocities and particle size in a PDI system or separately in a velocity-only system such as an LDV or LDA system.

In Doppler shift measurement systems, a well-characterized, narrow linewidth light source (laser) is used to illuminate one or more particles. Scattered light is collected from the particles in the field. Equation (10) shows that the frequency of the scattered light is shifted by the vector velocity of the particles in a direction related to the illumination direction and the collection direction,

$$f_{\mathrm{D}} = \frac{\vec{u}}{\lambda}(\vec{r} - \vec{S}) \tag{10}$$

where is $\vec{r}$ a unit vector in the direction of the collection optics, and $\vec{S}$ is the Poynting vector of the incident light.

Equation (11) shows that for typical values of $\vec{u}$ (50 m s^{-1}) and λ (532 nm), particles traveling toward the incoming beam, and the scattered light collected back along the direction of illumination,

$$f_D = \frac{\vec{u}}{\lambda}(\vec{r} - \vec{S}) = \frac{50\,\text{m s}^{-1}}{532\,\text{nm}} = 93.9\,\text{MHz} \qquad (11)$$

This represents a large absolute frequency, but it is relatively small compared with the base frequency of light at 532 nm ($\sim 5.6 \times 10^{14}$ Hz) or 1.67×10^{-5}% of the mean frequency. This Doppler shift frequency is clearly very small relative to the light frequency, which can make the shift difficult to detect directly. LIDAR systems typically make this measurement, using several different kinds of set-ups and filters to measure the frequency of the Doppler shift. LDV systems usually use a dual-beam arrangement, discussed below, which makes the electronic signals corresponding to the Doppler shift easier to detect.

4.1.1 Light Detection and Ranging Systems

For measurement of particle velocity, frequently as a marker for wind velocity, LIDAR systems have been developed which are capable of providing velocity data at long ranges (>10 km) from the source/detector. In general, these systems aim to gather the velocity of particles in some region illuminated by a laser beam, and measure an average velocity for the particles in the region. Depending on the specific technique, the particles may be droplets, dust, or molecules themselves. Figure 5 shows a comparison of the relative Doppler shift frequency widths from aerosol (particle) scatter and from molecular scatter.

Most of these systems rely on a Doppler shift of the laser frequency and subsequent determination of the magnitude and direction (relative to the laser line) of the shift to determine particle velocity. These systems are usually divided into coherent[22] and incoherent[23–28] systems, depending on the strategy used for detecting the Doppler shift. A schematic of a typical LIDAR system for velocity measurement is shown in Figure 6. In this method, a laser, usually a pulsed laser like a Nd:YAG (neodymium:yttrium aluminum garnet) (10–1000 pps, $\lambda = 1064$ or 532 nm), is the light source. A pulse of light leaves the laser and optical system, pointing at a region of interest. Scattering from airborne particles, like dust or water droplets, scatters laser light back along the path of the laser. An optical system collects the scattered light and focuses it onto a detector. The optical filtering of the collected scattered light is the key to this method. The frequency of the light has been Doppler shifted and perhaps broadened by the motion of the scatterers. The frequency of the Doppler shift is directly related to the particle velocity (towards or away from the source and detector).

Figure 5 Characterization of the scattered signal intensity for laser light scattered from aerosols and molecules in air for back scatter LIDAR systems. (Figure from McGill and Spirhine[22] and reproduced by permission of SPIE.) fwhh, full width at half-height.

Detection of the Doppler shift in these systems differs depending on whether the system is designed as "coherent" or "incoherent". For the coherent case, where the collected light is presumably sufficiently coherent that optical interference is possible, optical heterodyne or homodyne processes using the backscattered light and a reference beam are used. Typical examples[22] use a CO_2 (10.6 μm) or Nd:YAG (1.064 μm) laser as a probe beam, and a stabilized version of the same laser frequency (homodyne) or slightly shifted (heterodyne) mixed with the scattered signal at the detector. The mixing of the two lasers at the detector allows the slightly shifted light returning from the sample volume to interfere with the unshifted light from the reference laser. The resulting signal at the detector will exhibit, among other frequencies, a frequency of oscillation corresponding to the difference between the return beam frequency and the reference beam frequency. The pulse delay from the outgoing beam to the return beam gives the range of the sample (distance out and back) and the frequency detected is related to the velocity parallel to the sample and return beams.

Incoherent systems rely on frequency separation of the laser frequency from the Doppler shift frequency by wavelength filtering. Two different approaches use either a high-resolution interferometer (Fabry-Perot) or a steep cut-off wavelength filter.[23–28] Normally colored glass filters or interference filters are not narrow enough, although argon ion laser sources (514 nm) have used an iodine cell to filter out the 514 nm line very effectively, producing a narrow bandwidth line filter which attenuates the laser line significantly.[29] These types of detection do not require mixing at the detector and can use less strictly controlled and coherent laser sources.

Other filtering strategies include "edge" filtering in which the cut-off edge of an optical filter is characterized

Figure 6 Schematic of incoherent LIDAR system for airborne particle velocity measurement. (Figure from Fischer et al.[25] and reproduced by permission of SPIE.)

and used in the return signal from the LIDAR system with the calibration information to produce intensity values proportional to frequency, and therefore particle velocity.[23,24] For each of these cases, the actual measurement is usually of particle velocity for airborne aerosols ($d_p > 1\,\mu m$). A sample of a system and results from an incoherent system are shown in Figures 6–8. In these figures, individual locations provided measurements of wind speed over time to produce a space–time profile (Figure 7) or a vertical profile (Figure 8).

Alternatively, LIDAR methods can be used with molecular scattering ($d_p < \lambda$ or $d_p < 1\,\mu m$) and get similar types of results, although the scattering intensities and linewidths are quite different for the case of molecular scattering as noted in Figure 4. An example of molecular scattering using an incoherent system is shown in the work by Abreu et al.[24] It may be noted that for molecular scattering, since the particle size is much less than the wavelength of light, the type of scattering is called Rayleigh scattering. One evident characteristic of Rayleigh scattering is that the scattering cross-section varies as $1/\lambda^4$. Shorter wavelength sources therefore appear to be advantageous if molecules are the scattering target, and many newer LIDAR systems use second harmonic generated wavelengths of an Nd:YAG laser (at $\lambda = 532\,nm$) or the third harmonic of an Nd:YAG

Figure 7 Sample results for LIDAR systems for airborne particle velocity measurement. (Figure from Abreu et al.[24] and reproduced by permission of the Optical Society of America.)

Figure 8 Sample results for LIDAR systems for airborne particle velocity measurement. (Figure from Abreu et al.[24] and reproduced by permission of the Optical Society of America.)

($\lambda = 355\,\text{nm}$) to take advantage of the larger scattering cross-section at these shorter wavelengths.

4.1.2 Laser Doppler Velocimetry

LDV or LDA is among the most widely used particle or droplet velocity measurement techniques for single point measurement of particles. LDV has found applications in a wide range of situations from liquid to gaseous flows, for relatively dilute to fairly dense particle number densities, and for a wide variety of other relevant parameters.

A typical simple LDV system is shown in Figure 9. A laser source (usually a continuous-wave helium–neon, argon ion, or laser diode) is split into two parallel beams. The beams are focused to a single point, where particles are expected to appear. As a particle passes through the crossing volume in the plane of the crossing beams, photons are scattered simultaneously from each beam. From the geometry of the system, it may be evident that the photons scattered from beam 1, are frequency shifted (from Equation 11) as shown in Equation (12)

$$f_{D1} = \frac{\vec{u}}{\lambda}(\vec{r}_1 - \vec{S}_1) \tag{12}$$

Figure 9 Schematic of a simple LDV system.

Similarly, the photons from beam 2, are scattered by the particle with a frequency given by Equation (13)

$$f_{D2} = \frac{\vec{u}}{\lambda}(\vec{r}_2 - \vec{S}_2) \tag{13}$$

Scattered photons are collected on to a single point detector, typically a photomultiplier tube (PMT), and the resulting signal is processed to determine the frequencies present in the signal. Signal mixing of the coherent scattered light (amplitude addition) at the photocathode of the PMT results in frequencies given in Equation (14)

$$f_{net} = (\nu + f_{D1}) \pm (\nu + f_{D2}) = 0$$

or

$$f_{net} = 2\nu + f_{D1} + f_{D2} \tag{14}$$

Since the base laser frequency ν is well beyond the high frequency limit of the PMT, only signals proportional to the Doppler shift, f_D fall within the bandwidth of the detector and are recognized. Using the previous definition of Doppler shift, Equation (15) gives

$$f_{D1} = \frac{\vec{u}}{\lambda}(\vec{r}_1 - \vec{S}_1)$$

and

$$f_{D2} = \frac{\vec{u}}{\lambda}(\vec{r}_2 - \vec{S}_2) \tag{15}$$

the detected signal should look like

$$f_D = f_{D1} + f_{D2} = -\frac{\vec{u}}{\lambda}(\vec{S}_2 - \vec{S}_1)$$
$$= \frac{2u_x \sin(\kappa/2)}{\lambda} = \frac{u_x}{\delta} \tag{16}$$

and

$$\delta = \frac{\lambda}{2\sin(\kappa/2)} \tag{17}$$

where u_x indicates the velocity component in the plane containing the two laser beams, in a direction normal to the bisector of κ.

Combining Equations (16) and (17) gives Equation (18)

$$u_x = \frac{f_D \lambda}{2\sin(\kappa/2)} \tag{18}$$

where κ is the angle between the two incoming beams.

An alternative explanation for the operation of an LDV system, which is often offered, revolves around the formation of interference fringes at the point where the laser beams cross. A particle passing through the crossing region will scatter photons in the region of the crossing. The interference pattern fringe spacing is determined by the geometry of the LDV system. For initial parallel beam

spacing d_s, with a lens focal length f, the crossing angle is given by Equation (19)

$$\tan\frac{\kappa}{2} = \frac{d_s}{2f} \approx \sin\frac{\kappa}{2} \tag{19}$$

where the assumption of small κ is made.

The resulting crossing volume, assuming Gaussian laser beam cross-sections is estimated to have a diameter $d = 4f\lambda/(\pi d_{e^{-2}})$, and a length of $l = d/\tan(\kappa/2)$. The fringe spacing in the crossing region is given by Equation (20)

$$d_f = \frac{\lambda}{2\sin(\kappa/2)} \tag{20}$$

Since the time for a particle to pass between fringes is known from the optical signal, velocity is calculated from Equation (21)

$$u_x = \frac{d_f}{t_f} = \frac{f_D\lambda}{2\sin(\kappa/2)} \tag{21}$$

The results of these two perspectives on LDV signals are the same, as seen in Equations (18) and (21). A typical LDV set-up might have conditions shown in Table 4.

Table 4 Typical LDV system conditions

LDV system characteristic	Value
Laser	Argon ion (514 nm)
Beam separation	50 mm
Beam diameter	1 mm
Focusing lens focal length	250 mm
Sample volume dimensions (diameter and length)	$d = 0.16$ mm, $l = 1.64$ mm

While there are many different configurations for LDV systems, two important ones will be mentioned. For other configurations, some specialized to certain applications, the reader is referred to the references at the end of this section.

The first major modification to the simple geometry of the system described above, is the addition of some frequency-shifting to one or both of the laser beams. The goal of this shifting is to allow determination of velocity direction. In the simple system described above, particles with velocity components normal to the fringe pattern in the crossing volume are all evaluated as ''positive'' velocities, because they present an oscillating frequency at the output detector. Doppler shifts in frequency can be positive or negative about the laser frequency. Since the laser frequency appears as a time invariant signal, because its frequency is beyond the range of detectors, the Doppler shift frequency appears as positive or negative frequency shifts about the signal. Under these circumstances, positive and negative shifts appear the same. By frequency shifting one or both of the beams, an apparent motion of the crossing volume fringes at the frequency difference between the two beams superimposes a ''bias'' frequency on the fringe frequency from the scattered particles. The result is shown in Equation (22)

$$f_{deff} = f_d + f_s \tag{22}$$

where f_s is the frequency shift imposed on the beams. For $f_s > f_d$ the resulting f_{deff} can now indicate positive Doppler shift at frequencies above f_s and negative Doppler shift at frequencies below f_s. This frequency shift is usually accomplished using an acousto-optic modulator (also called a Bragg cell). A typical shifted and high pass

Figure 10 Typical LDV burst (with frequency shifting). This is a direct copy of an oscilloscope trace with a horizontal time base of 1 µs per division and a vertical gain of 20 mV per division.

filtered LDV signal is shown in Figure 10. This figure is taken directly from a digital oscilloscope. The vertical gain was set to 20 mV per division, and the sweep speed was 1 μs per division.

The second major change in configuration from the simple system outlined above is the use of fiber optics for delivery of the laser beams and transmission of the collected light from near the measurement volume to the detector. The use of optical fibers allows the laser and detector system to be mounted remotely from the experiment, with only a small number of optical elements near the actual sampling volume. With careful alignment, these systems can be made to operate as effectively as conventional delivery systems, and provide some system mounting and motion flexibility not easily available for conventional systems.[2,30]

More recently, many other innovations in LDV configurations have been successfully demonstrated, including laser diodes for the illumination source, solid-state detectors for collection, and advanced electronics for signal detection and analysis.

Analyzing the scattered light from particles in the crossing volume quickly and accurately extracting the frequency information is a challenging problem in signal processing and analysis. For low noise signals (as in Figure 9), estimating the frequency of the high-frequency portion to calculate velocity is relatively straightforward. Historically, this has been handled by special purpose electronics.

In more challenging environments, such as ones with significant background noise from laser light scattering off windows, surfaces, etc. these systems struggle to find particle signals with peaks sufficiently above a filtered noise floor to provide accurate velocity values. Newer processors rely on fast Fourier transforms (FFTs) or digital Fourier transforms, or related autocorrelation methods to extract burst frequencies in the presence of higher levels of background noise. These systems are all commercially available, and details of their operation are left to their respective manufacturers.

The LDV system described provides one component of the particle velocity vector. To obtain the other two components, additional optics may be included essentially replicating the one-dimensional system in three dimensions. Usually, to allow for simultaneous measurement of two or three velocity components, different laser wavelengths are used for each component allowing easy separation of the different scattering signals.

One common application for LDV systems or other velocity measurement systems is to make useful measurements of particle turbulence characteristics. The particles may be serving either as a marker for the continuous flow or may be of interest in their own right. A velocity measurement system like an LDV system provides a series of "instantaneous" velocity samples over some collection time window. While turbulence data are contained in the instantaneous samples, the volume and character of this kind of data makes it awkward to use in describing the flow in a concise way. As a result, instantaneous velocity values are often decomposed using "Reynolds averaging" as in Equation (23)

$$u_i = \bar{u}_i + u_i' \tag{23}$$

where u_i is the instantaneous velocity, $\bar{u}_i$ is an average, either time average, as in Equation (24),

$$\bar{u}_i = \frac{1}{\tau} \int_{t_0}^{t_0+\tau} u_i \, \mathrm{d}t \tag{24}$$

or an ensemble average, as in Equation (25)

$$\bar{u}_i = \frac{1}{N} \sum_{j=1}^{N} u_{ij} \tag{25}$$

Resulting data are often given as mean velocities ($\bar{u}_i$) and RMS ($\sqrt{\overline{u_i'^2}}$) values, normalized by an appropriate value.

A common extension to these basic velocity moments is the calculation of a timescale, called the "integral scale", which is considered to be an indication of the timescales for large-scale turbulence in the flow. The integral timescale, I_t, shown in Equation (27), is calculated from the autocorrelation coefficient, $\rho(\tau)$, shown in Equation (26)

$$\rho(\tau) = \frac{\overline{u_i(t)u_i(t+\tau)}}{\overline{u_i(t)^2}} \tag{26}$$

$$I_t = \int_0^{\infty} \rho(\tau) \, \mathrm{d}\tau \tag{27}$$

Results of mean velocities, RMS velocities, and integral timescales can be used for comparison with other flow conditions or other flows. It should be noted that the simple decomposition suggested by the Reynolds decomposition of Equation (22) is most useful for turbulent flows in which the mean flow is presumed to be steady, the flow is incompressible, and a "typical" turbulent energy cascade might be expected. For flows in which any of these assumptions is not valid, other more complex ways of defining a mean flow and the "turbulent" portion of the flow (and related turbulent characteristics) may be needed.[31]

A sample of LDV results for a turbulent flow downstream of a rearward-facing step is shown in Figures 11, 12, and 13.[33] The flow is a steady water channel flow over a step (an abrupt expansion). This is a common test problem for instrumentation and modeling systems as it involves a largely two-dimensional shear

Figure 11 Sample LDV results for water flow over a rearward-facing step. This figure shows mean axial velocity profiles at various distances downstream of the step. (Figure from Etheridge and Kemp[31] and reprinted by permission of Cambridge University Press.)

Figure 12 Sample LDV results for water flow over a rearward-facing step. This figure shows mean transverse velocity profiles at various distances downstream of the step. (Figure from Etheridge and Kemp[31] and reprinted by permission of Cambridge University Press.)

flow with separation and recirculation downstream of the step. Figure 11 shows several mean (time average) profiles at different locations downstream of the step, where x is the axial dimension, y is the vertical dimension, and H_s is the step height. In this experiment, cross-stream velocities were also measured separately by rotating the LDV system, and sample mean results are shown in Figure 12. Figure 13 shows normalized RMS values for the turbulence for both x and y velocity components.

There are many other examples of LDV results in journal literature. Since application details may vary depending on specific application, further examples will be left to journals in the respective field of interest.

Before leaving this overview of LDV systems, some cautions regarding the constraints and biases in LDV measurements should be mentioned. As may be surmised, the LDV system expects only one particle to be in the crossing volume at any one time. If more than one particle is present, the actual frequency sampled is not likely to be related to the particle velocities in the form of Equation (21) unless the particles happen to have the same vector velocity in the plane of the illumination beams normal to the center line of the beams. Most signal processors go to great lengths to identify and discard data from multiple particles in the control volume. Clearly this presents a problem for very dense particle fields in which the likelihood of multiple scatterers in the control volume is high.

Since the actual time of appearance of a particle in the measurement volume is somewhat random, evaluation of LDV results is usually approached statistically. The underlying assumption (hope?) is that the particles which did pass through the control volume, and whose signals passed all the processor tests, are representative of all "similar" particles in the flow field.

For LDV measurement systems, there are several major expected biases in the velocity signal. One of these arises from relative oversampling of the higher velocity particles, since they are more likely to pass through the control volume than lower velocity particles in a given sample time. A second bias is size biasing, in that larger particles can have an effectively larger detectable control volume than do smaller particles because of their larger scattering signal even in the weaker portions of the Gaussian probe beams. Note that simultaneous measurement of particle size and velocity allows users to access velocity–size correlations and assess the significance of this size bias. A third bias is velocity average biasing, in that standard time averages of particle velocities may overrepresent some samples because of the irregular arrival times (hence integration times) for particles in the system. There are methods to minimize the effects of these biases, and interested readers should consult appropriate references to understand the implications of these biases for the experiments of interest.[2,17]

4.2 Direct Imaging Methods

Probably the most straightforward way of measuring particle velocity is to record an image of the particle of interest at a known time, and record a second image at some later time. An estimate of the displacement of the particle between the two images is available from the images, and combined with the known time between the two recordings, an average velocity can be calculated. Implementing this method in realistic particle or droplet

Figure 13 Sample LDV results for water flow over a rearward-facing step. This figure shows fluctuating axial and transverse velocity profiles at various distances downstream of the step. (Figure from Etheridge and Kemp[31] and reprinted by permission of Cambridge University Press.)

flows is frequently far from straightforward. Depending on many of the parameters of the flow and particles, different strategies may be needed to successfully acquire velocity data. In the end, direct imaging of particles for velocity measurements is not merely one technique, but a whole family of techniques for the range of situations of interest.

Many of the techniques used for direct imaging are relatively new, and several recent review papers provide a thorough background and reference list of recent fundamental and applied work in this field.[10,34–36] In this section, some of the different approaches to direct imaging will be described and some of the choices that users need to make in selecting a specific technique will be indicated. In many cases, constraints on the techniques available for direct imaging are related to current hardware and software limitations. As new hardware and software with greater capabilities become available, some of the current limitations on direct imaging will change and the optimal system for a given application will likely change, too.

In the following paragraphs, I will outline some of the major features of a particle field which impact how a direct imaging experiment might be performed, and some of the

choices available to experimenters which also impact the type and quality of the results.

4.2.1 Particle Visibility

Recording a particle image requires an adequate number of photons to be scattered from a particle into the collection optics and system detector. The scattered intensity, as noted in an earlier section, is a function of particle size, index of refraction, shape, and collection direction and solid angle, among other things. As was discussed in the previous section, for particles near or greater than the wavelength of light to be used, LMT provides useful estimates of the spatial variation of scattered light intensity for various particle sizes and indexes for spherical particles. With a few exceptions, there are not many predictive results on scatter for nonspherical particles.

The range of particle visibilities is very large; for near-forward scatter directions, Mie scatter intensities vary approximately as d^2 (recall Figures 1–3, for example). In many polydisperse particle fields, a size distribution of an order of magnitude in particle diameter is likely (say 10–100 μm), giving a range of scattering intensities of at least 1 : 100. This range is not particularly large for a size range, but may present some difficulties for image recording for limited dynamic range detectors like 8-bit (256 gray-level) charge-coupled device (CCD) cameras. For velocity measurement, accurate image size may not be essential or necessary as long as the image size is constant and relatively small. A wide range of particle visibilities presents the likelihood of size biasing the velocity statistics, in that the more visible larger particles are more likely to be seen and therefore will represent a higher proportion of the distribution of velocity samples than they represent in the actual particle system. If larger particles have different velocities from smaller particles (as is likely) the velocity mean and standard deviation will be affected by the sampling.

4.2.2 Particle Size

While particle size affects visibility, it also affects the minimum displacement that can be measured accurately for most of the analysis schemes, as this minimum displacement is some significant fraction of the particle size. In addition, for situations in which the particle is seeded into the flow as a marker, the size affects the ability of the particle to follow the continuous phase of the flow and provide an appropriate velocity value. This issue is the same one commonly considered for LDV measurements in flows.

4.2.3 Particle Density

Depending on the number of particles in an imaging volume and their distinguishability, different methods may be required to extract velocity data from a set of images. Particle density is clearly a function of the particle loading in the region of interest (i.e. particles cm^{-3}) but for imaging, the number of particles in the image volume may be more relevant. For dilute particle fields, individual particles can be identified and ''tracked'' from image to image, making a particle tracking velocimetry (PTV) system. For dense particle fields, obtaining an undistorted image of the particle region of interest may be difficult. In addition, as particles are unlikely to be distinguishable from one another in a sequence of images, an area average analysis for the particles falling in a region of the flow is usually used. Dense particle fields may cause significant attenuation of the illumination beam, leading to stronger scattering signals from some regions of the field than from others. Imaging through dense particle fields can also be somewhat problematic.[37]

4.2.4 Particle Image Density

For imaging of particles, we normally assume that there will be little or no particle image overlap; actual experiments may impose a more severe requirement in that identifying particles in different images and ''matching'' the same particle between two images may be difficult if the particle image density is high. Actual particle density as well as the total particle volume collected in the image affect particle image density.

4.2.5 Particle Velocity

Since particle displacements are the actual measurement, expected particle velocities and the range of velocities will affect the choice of experimental parameters, like the time between images. This is because displacements that are quite small (less than a particle diameter) or quite large (>1/3 the ''interrogation spot size'') may cause problems in measuring displacement.

4.2.6 Imaging System Characteristics

These characteristics include system magnification, resolution, aberrations, field size, working distance, and framing rate among others. Clearly, many of these characteristics are interrelated, but they affect the image quality, and the apparent particle size, displacement, and dynamic range. Commercial 35 mm format or medium format lenses of very high quality and moderate price are available for the optical imaging system. The specific characteristics of the selected imaging system along

with the detector characteristics will determine the system characteristics and aberrations. Typical choices of detectors range from conventional 35 mm cameras using high-contrast silver-halide film, to solid-state CCD detectors. Very high spatial resolution and/or large dynamic range systems typically operate at relatively slow speeds (imaging rates), while some lower resolution systems can operate at high imaging rates. These rates can range from less than one image s^{-1} (cooled 1000 pixel by 1000 pixel or more, by 16 bit, CCD slow scan) to 4500 images s^{-1} (256 pixel by 256 pixel CCD) to over 200 000 frames s^{-1} (drum camera with effective 16-mm image size on film). As new hardware is developed, particularly in the solid-state sensor area (CCD cameras), higher resolutions (e.g. 4 K pixel by 4 K pixel is now available), with large dynamic ranges (12 or 16 bit), at faster framing rates (>30 fps) will become available. Because of the trade-offs in the imaging system, clear system requirements are needed before specific hardware is selected. Conversely, access to state-of-the-art hardware may make the trade-offs in temporal and spatial resolution less limiting.

4.2.7 Illumination System Characteristics

Many issues regarding spatial and temporal resolution in the direct imaging system are affected by choice of illumination system and the associated illumination optics. A common choice for high-velocity particle imaging (say particle velocities $> 10\,m\,s^{-1}$) is a pulsed laser, like a Nd:YAG (10 ns pulse length, 10–1000 Hz, $\lambda = 532$ nm or 355 nm) which is formed into a thin ($\sim$500 μm) sheet to illuminate one plane of particles. For many experiments, the desired time between pulses is frequently so short that the standard repetition rate for the laser is too slow. This may require more than one laser synchronized together, or some clever modifications to the Q-switch circuitry to obtain two or more pulses with a time between pulses of the order of 10–100 μs. For lower-velocity particles, a continuous-wave laser source may be satisfactory, since continuous-wave lasers can be shuttered mechanically or acousto-optically with microsecond precision.

Other requirements for the illumination source may include specific wavelengths for fluorescent particles (pumping an absorption band for the particle, then imaging a fluorescence wavelength to improve particle visibility),[38] different pulse lengths (e.g. longer pulses for lower power density to conserve optics and windows), and polarization selection.

4.2.8 Interrogation or Analysis System

Once a pair or more of particle field images have been captured, evaluating the particle displacement between the two images can be done a variety of ways. As there is extensive literature on many aspects of this ''interrogation'' problem, readers are referred to the references, and only outlines of some strategies will be suggested here.

For relatively low particle density images, PTV analysis schemes can be used.[36,39] These schemes usually rely on large particle-to-particle spacing allowing individual particles to be easily identified in each image and from image to image. Finding the particle velocity is a matter of tracking the particle images and calculating the displacements from image to image of the identified, ''paired'' particles. The result of this kind of interrogation of a set of images is a set of vectors for each particle pair, indicating velocity direction and magnitude. Since the method requires that there be relatively few particles in each image, only a few vectors result from each set of images. To build a spatially ''complete'' set of vectors that covers a significant portion of a volume of interest, a large number of replicates of the experiment may be required.

Data analysis methods for PTV focus on following particles from image to image, and ensuring that a single particle is ''matched'' with its corresponding image in other image frames. Two- and three-dimensional velocity vectors can be obtained with these methods.

For relatively high particle density images, PTV is difficult since the particles in each image cannot be easily ''paired'' with their images (i.e. all particles look alike). To overcome this identification problem, the solution sought is changed slightly. Rather than seeking a vector for each particle, we may be content to seek an average (or most probable) velocity or particle displacement in a small region of the flow. There are two major approaches to finding this local average particle displacement. They differ primarily in terms of what kind of image information is available. One approach, known as an autocorrelation approach, begins with both particle images (separated by some Δt) superimposed, as might be the case for a double exposure on film or a solid-state detector. The second approach, known as the cross-correlation approach, begins with independent first and second images, as for consecutive images of the particle field.

Briefly, the autocorrelation approach selects a small region of the double exposure image to interrogate (interrogation region). Typical interrogation region sizes might be 1 mm in diameter or 1 mm by 1 mm square. The result of this data analysis will be an average particle velocity and direction over this interrogation spot size for all particles that lie within the spot and have a second image also lying within the spot. The autocorrelation of the interrogation spot with itself should provide information on the most probable displacement

of particles in the region. The strongest correlation should be all particles with themselves, at zero displacement. The next strongest correlation of particle images in the spot should, we expect, correspond to the most frequent spacing between particles. Assuming the initial particle spacing in either of the two exposures is random, the most probable spacing (which is not random) should be the displacement that all particles underwent between the exposures of the first image and the second image. In general, the autocorrelation is given by Equation (28)

$$R(\vec{s}) = \int I(\vec{x})I(\vec{x}+\vec{s})\,\mathrm{d}\vec{x} \tag{28}$$

While this can be analytically calculated for each interrogation spot, it is usually more convenient to invoke the fact that for a function $f(x)$ with Fourier transform $F(s)$, $\int_{-\infty}^{\infty} f^*(x)f(x+u)\,\mathrm{d}x$ has a Fourier transform of $|F(s)|^2$.[40] The utility of this theorem is that while calculating autocorrelations for many interrogation spots in an image may be rather slow, calculating Fourier transforms using the FFT may be significantly faster. As a result, most autocorrelation schemes for particle image velocimetry (PIV) calculate the autocorrelation using the following sequence:

Select interrogation spot

$\Rightarrow$ "snap" image of spot

$\Rightarrow$ two-dimensional FFT of image

$\Rightarrow |F_{2D}(s)|^2$

$\Rightarrow F_{2D}^{-1}|F_{2D}(s)|^2$(inverse two-dimensional FFT)

$\Rightarrow R(\vec{s})$

Once the two-dimensional autocorrelation is acquired, the largest peak outside of the $\vec{s} \approx 0$ region should give the value corresponding to the average particle displacement. Suggestions for optimizing imaging, interrogation, and "peak finding" are given by Keane and Adrian.[20]

Autocorrelations have been widely used in PIV. They are typically calculated digitally,[41,42] but with an appropriate set-up may be "calculated" using an optical correlator.[43] A major drawback of autocorrelation methods is that while velocity magnitude and direction can be obtained, the sense (positive or negative value of velocity) of the velocity cannot, because with double exposure images, it is not known which set of particle images corresponds to the "first" image, and which the "second". When the two images are recorded separately, this information is available and can be used with cross-correlation to remove the 180° ambiguity of direction. The image separation may be accomplished by recording each of two images on separate pieces of film or separate solid-state detectors, or by tagging one set of images. The most common tagging method is by color. For example, if two different color pulsed lasers are available, they may be synchronized such that one provides the illumination for the first set of particle images, and the second laser provides the illumination for the second set. If the images are recorded on a color sensitive detector or film, they may be later separated into a "first" and "second" image.[44]

Performing a cross-correlation of particle images in a region of the total image with a similar region in the second image should produce a maximum cross-correlation value when the first image subset and the second subset are offset by the most probable displacement of the particles in the region. The cross-correlation typically used is defined[45] in Equation (29)

$$\phi_{fg}(m,n) = \sum_{k=k_{\min}}^{k_{\max}} \sum_{l=l_{\min}}^{l_{\max}} f(k,l)g(k+m,l+n) \tag{29}$$

where $f(k,l)$ represents the intensity values at pixels locations x_k and y_l in the first of the two images, and $g(k,l)$ represents the intensity values at pixels locations x_k and y_l in the second of the two images. The correlation essentially searches for the offset (m,n) of $g(k,l)$ with respect to $f(k,l)$ which produces the largest sum over the region. The offset corresponding to this peak is taken to be the average displacement of particle images in the region.

This process of cross-correlation continues with successive subregions of the image, sometimes with overlap of the image subsets, until the entire image has been sampled. As with autocorrelation methods, this calculation is usually performed using FFTs because the numerics are much faster than direct calculation of the cross-correlation. The sequence of operations is similar to that for autocorrelation, except two-dimensional-FFTs of each of $f(k,l)$ and $g(k,l)$ are needed at the beginning to produce the cross-correlation in Equation (28) after the last two-dimensional inverse fast Fourier transform (IFFT).

4.2.9 Particle Image Velocimetry Example

One example of direct imaging systems using particles as markers for flows will be shown. This example relates to the flow inside an internal combustion engine which is expected to have relatively high mean flow velocities ($50\,\mathrm{m\,s^{-1}}$) and high turbulence levels (>50%).[46] The spatial scales of interest range from the full size of the flow chamber (100 mm × 100 mm × 100 mm) to smaller scales of turbulence (<1 mm). The mean flows are unsteady, varying at frequencies of up to about 1 kHz, with small-scale variations at 10 kHz or greater. Additionally, the

flow is not precisely repeatable (cycle-to-cycle variation), so replicates from different engine cycles have neither the same mean value nor the same turbulent statistics. The interest is to acquire velocity data with a reasonably high spatial resolution (1 mm × 1 mm × 1 mm) and temporal resolution (100 μs).

This application of PIV methods to engine flows is in general similar in concept to the previous PIV work by Adrian[10] and engine work by Reuss et al.[41] and Reeves et al.[42] but differs in implementation and detail. The PIV method implemented here includes a data recording step with a double pulsed Nd:YAG laser as a light source, and an analysis step using an optical Fourier transform method to estimate particle displacement.

The particular flow of interest in this example was the gas flow near the periphery of a spray plume from a fuel injector. The spray chamber is a cylindrical chamber, about 150 mm in inner diameter, with the injector mounted at one end of the cylinder. The opposite end of the cylinder had a 100-mm fused silica window, and a small window was available at the periphery for introducing the laser light. The chamber is operated at room temperature, and is typically pressurized with argon to about 20 bar. Two frequency doubled Q-switched Nd:YAG lasers were used as illumination sources for the particle image recording. Balanced double pulses were obtained with a 6 ns pulse width and 20 μs pulse separation time. The laser beam was formed into a sheet and passed into the test section through the side so that the flow region of interest could be photographed through the large front window. The sheet thickness was about 0.5 mm and the beam height was about 25 mm. A 35 mm format camera was used to take the PIV photographs on Kodak Technical Pan 2415 film. TiO_2 was mixed with air in a particle generator and was mixed into the chamber with the argon.

A sample of the particle images and resulting auto-correlation based velocity vectors are shown in Figure 14. In this figure, the spray plume is clearly visible. Near the spray plume, small droplets may mix with the seed particles and the velocity in those regions is likely to be an average of the small droplet velocity and small seed particle velocities.

For turbulent flows, PIV or other direct imaging methods can provide detailed time-series data and resulting statistics, but with considerable difficulty. To produce a time series of velocity vectors at a point in a flow requires a statistically significant number of realizations (image pairs) at that location in the flow. Direct imaging systems do provide spatial information in each image, so spatial turbulence information is readily available, as opposed to temporal turbulent data single point systems like LDV provide. With spatially

Figure 14 Sample PIV image from TiO_2 seeded gas in a closed pressure vessel. The flow is generated by a high-pressure fuel spray (seen in photograph). Velocities of interest are of entrained gas flow. A vector plot shows the measured particle (gas) flow velocities around the liquid jet.[46]

varying velocity vectors, instantaneous, spatially varying vorticity and strain rate values can be calculated.[41] Using the spatial autocorrelation, in analogy to the temporal autocorrelation of Equations (25) and (26), an integral length scale could be calculated for the region of velocity vectors. For replicates of an experiment, these spatially varying turbulent quantities can be compiled into spatial and temporal values, using spatial and temporal averaging as appropriate to the application.

4.3 Recent Developments in Particle Image Velocimetry

Recently, direct imaging methods, and, in particular, PIV methods have expanded into three-dimensional velocity vector measurements. These systems usually employ two or more imaging systems to produce stereoscopic images or in a quite different approach, use holographic recording to allow for three-dimensional reconstruction of the image field.

The stereoscopic methods rely on the same basic imaging approaches outlined for the two-dimensional approaches discussed above, with some additional

complexity in imaging system set-up and subsequent data analysis to extract three-dimensional vectors from nonorthogonal data.[47]

Holographic recording of particle images for reconstruction and evaluation of three-dimensional particle velocities is more complex than the stereoscopic approaches, but promises more than a single plane of three-dimensional vectors. These systems are still under development in research laboratories. Interested readers may find some discussion of holographic PIV in recent literature.[48–50]

5 SUMMARY

The field of particle velocity measurement is very large, with a wide range of techniques available. In many cases, the most useful techniques turn out to be optical methods because of their accuracy, nonintrusive character, and ability to be applied remotely to a flow. In this article several characteristics of the particles (distributed phase) and the background fluid (continuous phase), which may be relevant in selecting a particle measurement method, have been outlined. Three of the most commonly used particle velocity measurement methods have been discussed. Readers interested in applying any of these are encouraged to take this section as an introduction and to dig deeper into the method and applications specific to their field of interest. Hopefully the introduction provided here and the short list of references will provide a good starting point from which potential users can further explore these and other techniques.

Separation and Analysis of Peptides and Proteins: Introduction

Christian Schöneich
University of Kansas, Lawrence, USA

Rapid advances in molecular biology, medicine, and the various genome projects will continue to demand new analytical methods and the improvement of existing techniques for the rapid and reliable analysis of peptides and proteins.[1] Complex mixtures of peptides and proteins will be derived from cell lysates and body fluids. Several or all components of these mixtures shall be simultaneously characterized and quantified avoiding lengthy purification schemes for the individual components. Protein samples containing only one gene product may be quite heterogeneous depending on the degree and manifold of potential posttranslational modifications. Such modifications may be predictable based on known target sites for phosphorylation, sulfation, glycosylation, ubiquitinylation etc. However, proteins may also suffer additional, non-enzymatic, chemical modifications such as the deamidation of Asn (to L- and D-Asp, and L- and D-isoAsp),[2] oxidation, β-elimination, and racemization.[3] The latter processes are usually encountered during protein purification or long-time storage in pharmaceutical formulations. Some parameters controlling these non-enzymatic pathways have been established, according to which the most sensitive amino acids can be predicted. For example, 'deamidation hot spots' are located in flexible protein regions, predominantly when Asn is followed by a Gly residue.[4] Nevertheless, there is considerable uncertainty with regard to the most sensitive positions affected by the other degradation pathways. For example, solvent exposure is an important parameter controlling Met oxidation in proteins by peroxides but, in some cases, the metal-catalyzed oxidation of these proteins targeted especially the least accessible regions which, however, contained several metal-binding residues in the vicinity of the affected Met residues.[5] Diastereoselective product formation can add complexity to the analytical task. Asn deamidation can yield two enantiomers of each product, Asp and isoAsp[2] (diastereomers, if these products are components of polypeptides). Met oxidation yields two MetSO diastereomers, Met-d-SO and Met-l-SO.[6] γ-Irradiation of protein samples, important for pharmaceutical or food sterilization processes, can essentially racemize every amino acid at Cα.[7] Finally, D-amino acids are an important component of peptide drugs designed for longer biological half lives. In the majority of the cases, the resolution of posttranslational modifications, including the respective enantiomers or diastereomers, can be achieved by one of several modes of high-performance liquid chromatography (HPLC) or capillary electrophoresis. Therefore, the present section includes the following articles on various modes of HPLC and capillary electrophoresis, important for the separation of peptides and proteins (see also the separate section on *Liquid Chromatography*): **Reversed-phase High-performance Liquid Chromatography in Peptide and Protein Analysis; Hydrophilic-interaction Chromatography in Peptide and Protein Analysis; High-performance Liquid Chromatographic Separations and Equipment in Peptide and Protein Analysis, Miniaturization of; Capillary Electrophoresis of Peptides; Capillary Electrophoresis of Proteins and Glycoproteins; Capillary Electrophoresis in Peptide and Protein Analysis, Detection Modes for; Posttranslational Oxidative Modifications of Proteins**. Often, proteins are subjected to proteolytic digestion, so that individual peptides and their potential modifications can be resolved ('peptide mapping'). An important detail of the peptide mapping procedure is that, depending on the nature of the protein substrate, proteases may show nonspecific cleavage sites. Moreover, posttranslational modifications may lead to conformational changes of the affected proteins, which can affect the accessibility of cleavage sites. Thus, proteolytic digestion shall be carefully optimized and validated, and a chapter in this section introduces the reader to the various aspects of peptide mapping, **Proteolytic Mapping**. A separate article has been devoted entirely to the **Peptide Diastereomers, Separation of**. Mass spectrometry has advanced to become one of the most powerful tools in the analysis of peptides and proteins, largely due to the availability of soft ionization techniques such as electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI). The potential of mass spectrometry in the analysis of peptides and proteins is reviewed in three chapters in this volume: **Capillary Electrophoresis/Mass Spectrometry in Peptide and Protein Analysis; High-performance Liquid Chromatography/Mass Spectrometry in Peptide and Protein Analysis; Matrix-assisted Laser Desorption/Ionization Mass Spectrometry in Peptide and Protein Analysis** (for more details, see also the section *Mass Spectrometry*).

A fundamental task in protein biochemistry is the analysis of protein function, structure, and dynamics. A clean analysis of these parameters requires homogeneous protein samples, conveniently monitored by gel electrophoresis. Hence, we have included an article on **Gel Electrophoresis in Protein and Peptide Analysis**, together with articles on **Protein Purification: Theoretical and Methodological Considerations** [see also **Proteins and Peptides Purification in Pharmaceuticals Analysis** in

Encyclopedia of Analytical Chemistry

the section *Pharmaceuticals and Drugs*] and the **Chromatography of Membrane Proteins and Lipoproteins**. The structural analysis of proteins requires one of several possible diffraction techniques, and the article **X-ray Crystallography of Biological Macromolecules**, introduces the reader to various aspects of protein crystallization and X-ray crystallography. Certain structural characteristics of peptides and protein such as, e.g. the extent of α-helical and β-sheet conformation, can be quantitatively measured in solution by circular dichroism (CD) or Fourier transform infrared spectroscopy (FTIR). In this section, we have included an article on **Fourier Transform Infrared Spectroscopy in Peptide and Protein Analysis** [see also the section *Infrared Spectroscopy*] while an article on **Circular Dichroism in Analysis of Biomolecules** can be found in the section on *Biomolecules Analysis*. In particular, the FTIR experiments are also possible with solids, permitting the assessment of protein structural changes as a result of processing, e.g. freeze-drying. Protein structure and dynamics can be investigated by means of nuclear magnetic resonance (NMR), electron spin resonance (ESR) and fluorescence spectroscopy (where the latter two techniques require the covalent attachment of a spin or fluorescent label, respectively). In this section, the reader will find an article on **Electron Spin Resonance Spectroscopy Labeling in Peptide and Protein Analysis** and **Fluorescence Spectroscopy in Peptide and Protein Analysis**. The **Nuclear Magnetic Resonance of Biomolecules** and **Glycoprotein Analysis: Using Nuclear Magnetic Resonance** are covered in the sections on *Biomolecules Analysis* and *Carbohydrate Analysis*, respectively. More information on the NMR and ESR techniques can be found in the section *Nuclear Magnetic Resonance and Electron Spin Resonance Spectroscopy*. Many proteins function through the interaction with biomolecules such as other proteins, lipids, and/or (poly)nucleotides. Moreover, proteins play an active role in the binding and transport of many drugs. Therefore, we have included articles on **Protein–Oligonucleotide Interactions**, and **Protein–Drug Interactions**. A relatively novel technique to measure binding equilibria of proteins is surface plasmon resonance spectroscopy, covered in the article **Surface Plasmon Resonance Spectroscopy in Peptide and Protein Analysis**, which has the advantage that it can specifically measure on- and off-rates of the binding process. Finally, more insight into the dynamic processes of proteins may be obtained by molecular modeling techniques, which, however, strongly benefit from experimental data which can be used as constraints in order to speed up or bias the modeling process. This topic is covered in the article **Molecular Modeling in Peptide and Protein Analysis**.

ABBREVIATIONS AND ACRONYMS

CD	Circular Dichroism
ESR	Electron Spin Resonance
ESI	Electrospray Ionization
FTIR	Fourier Transform Infrared Spectroscopy
HPLC	High-performance Liquid Chromatography
MALDI	Matrix-assisted Laser Desorption Ionization
NMR	Nuclear Magnetic Resonance

Capillary electrophoresis (CE) is a highly efficient separation technique which achieves high resolution with low sample consumption. Crucial to any separation technique are detection modes capable of giving useful data about separated analytes, including both quantitative and qualitative information. A variety of general detection modes for CE have been developed, most based on similar systems used in high-performance liquid chromatography (HPLC), but only some are useful in the analysis of peptides and proteins. Modes which are selective for certain spectral or chemical properties of these analytes are often employed. The absorption of ultraviolet/visible (UV/VIS) light as well as fluorescence (Fl) fit into the former category while electrochemical (EC) detection falls under the latter. The development of mass spectrometry (MS) as a detection mode for peptide and protein analysis may be the ideal choice since a great deal of qualitative information can be obtained and used for identification and structural characterization. By definition, CE involves separation in a ''micro'' environment, a capillary, and this places certain demands on the performance of the detection system and perhaps the greatest challenge is that of sensitivity.

Encyclopedia of Analytical Chemistry

1 INTRODUCTION

There are a variety of detection modes for CE and most of these are at least theoretically applicable to the detection of peptides and proteins. Of these detection methods, those which measure some universal property, such as refractive index or conductivity, are not generally useful. On the other hand, detection methods which depend on some property of the peptide or protein which allows differentiation from the background electrolyte and other sample components are of great utility. Thus, detectors sensitive to the absorption of UV/VIS electromagnetic radiation, Fl emission or EC activity are all used. Detection by MS is extremely powerful and can also function selectively by monitoring ions of a particular mass.

Some detection methods deserve special consideration since they can supply additional information about an analyte useful in its identification and characterization. MS and multiwavelength or scanning UV/VIS detectors provide such information. Obviously, the availability of commercial systems with such detectors and ease of use are of concern when selecting a method, prompting careful thought about the use of MS or EC detection.

The sensitivity provided by the detection method can be of paramount importance if the peptide or protein is present in low concentrations and cannot be concentrated sufficiently prior to analysis by off- or on-column techniques. This is particularly important for UV/VIS absorbance detection owing to the small optical pathlength encountered in CE. Derivatization of peptides or proteins to provide fluorescent tags provides increased sensitivity and, often, selectivity.

2 DIRECT DETECTION

2.1 Ultraviolet Detection

For underivatized samples, the most prevalent method of detection is ultraviolet (UV) absorbance detection in the 200–230 nm range, which is primarily due to the presence of amide groups necessarily present in all peptides and proteins. This is evidenced by an inspection of data presented in a recent handbook on the application of CE to protein and peptide analysis. Of the 80 applications cited[1,2] for protein analysis by capillary zone electrophoresis (CZE), micellar electrokinetic chromatography (MEKC) and capillary gel electrophoresis, 75 used detection wavelengths in the 200–230 nm range. Of the remainder, four used UV absorbance detection at other wavelengths while one used Fl detection. However, when capillary isoelectric focusing (CIEF) is used as the mode of CE separation, 10 out of 12 applications monitored absorption at 280 nm. Proteins

will show an absorption maximum at this wavelength owing to the presence of aromatic amino acids, and use of 280 nm detection avoids the problem of a high background absorption in the low-wavelength UV range due to the ampholytes utilized in the separation medium. Unfortunately, 280 nm detection results in a loss of sensitivity compared with detection near 215 nm and this requires higher concentrations of proteins to be used. This, in turn, may result in precipitation of focused proteins.[3] If CIEF is used to analyze peptides that do not contain aromatic amino acid residues, an alternative, low-cost method which uses a universal detector that senses refractive index gradients can be employed and has been demonstrated to be effective in the analysis of tryptic digests of bovine and chicken cytochrome c.[4] Of the 59 applications cited[5] for the analysis of peptide hormones and model peptides, 47 used detection wavelengths in the 200–230 nm range. Of the remainder, four used UV absorption at other wavelengths, four used Fl, two EC, one MS and one refractive index detection methods.

UV detection systems, including multiwavelength detectors, are commonly found in commercial CE systems and are relatively rugged and easy to use. Multiwavelength detectors such as scanning and photodiode-array detectors are used routinely because of certain advantages that they provide. For example, in a report on the refinement of a protein assay by CE for apolipoprotein A-I, a major indicator of arteriosclerosis, multiwavelength detection (Figure 1) indicated that a significant increase in the sensitivity of the method could be achieved by utilizing 195 nm detection rather than the commonly used 200–220 nm range.[6]

The main problem associated with UV detection is the relatively low concentration sensitivity, typically exhibiting a limit of detection in the low-micromolar region for small peptides.[7] Although the use of extended optical pathlength capillaries, available from commercial vendors, can increase sensitivity by an order of magnitude, further increases in sensitivity can be obtained most readily by using a different detection method.

2.2 Fluorescence Detection

Detection of fluorescent emission offers an inherently more sensitive method than UV absorption detection. Direct Fl detection of peptides and proteins is dependent on the presence of two amino acid residues, tryptophan and, to a lesser extent, tyrosine. Unfortunately, these are not particularly strong fluorophores and an even greater limitation is that their excitation range is in the 210–290 nm wavelength range, which is well outside the 488-nm argon-ion laser or the 594-nm helium–neon lasers used in commercial instruments. Nonetheless, in-house detection systems have been used for analysis

Figure 1 Multiwavelength electropherogram of a normal human serum sample (dilution 1 : 30) spiked with 0.25 mg mL^{-1} apolipoprotein A-I. Peak 1 is albumin and peak 2 is apolipoprotein A-I. (Reproduced from W. Voelter, J. Schutz, O.E. Tsisiloni, A. Weiler, G. Grubler, G. Paulus, S. Stoeva, R. Lehman, 'CE in Biochemical and Clinical Laboratories: Selected Attractive Examples', *J. Chromatogr., A*, **807**(1), 135–149 (1998), Copyright 1998, with permission from Elsevier Science.)

with detection limits in the low-nanomolar range[8,9] for peptide analysis. Even lower limits (200 pM) have been reached[10] for selected peptides with high tryptophan content. Additionally, this detection method permits the acquisition of emission spectra, affording discrimination between peptides containing tryptophan and/or tyrosine.

In general, derivatization of peptide or protein with a fluorescent tag conducive to detection with commercial detectors is the preferred method for sensitive detection. Direct Fl detection is probably confined to use for samples containing tryptophan or tyrosine residues where the additional demands inherent in the derivatization process, such as sample handling, dilution of sample and background Fl introduced by the derivatizing reagent, are undesirable. Such an example is found in the analysis of hemoglobin variants in single cells.[11]

2.3 Electrochemical Detection

The potential of EC detection as an alternative method to UV absorbance detection to enhance sensitivity is indicated by the success of EC detection in HPLC. One EC detection method is based on a traditional method used for determining protein concentrations in biochemical analysis – the biuret reaction. In this method,[12] the wall of the capillary is loaded with Cu^{2+}

ions by a rinse procedure and peptides migrating through the column form complexes with Cu^{2+} ions released by the interaction. The complexes are then detected at carbon fiber microelectrodes yielding detection limits as low as 700 nM. Of interest is the fact that this method can be applied to the detection of cyclic peptides. Sensitive detection of this class of peptides is important because they often cannot be detected by Fl methods since they lack a free amino group which is the functionality required for labeling by most fluorescent reagents. An alternative method for the detection of these molecules was demonstrated using a mixture of two cyclic pentapeptides obtained from solid-phase synthesis which were separated by CE with EC detection at a copper electrode.[13]

Other EC detection methods reported include the analysis of bovine serum albumin using a carbon fiber microdisk array electrode[14] and cytochrome c using a gold microdisk array electrode modified with cysteine.[15] The potential of pulsed amperometric detection (PAD) at a high pH was demonstrated on a mixture of peptides released from recombinant coagulation factor VII by treatment with a glycopeptidase.[16] By using integrated pulsed amperometric detection (IPAD) under mildly basic conditions (pH 9), mass detection limits in the picomole range were observed.[17] EC methods based on the detection of thiols present in many peptides, such as glutathione, have been developed using modified electrodes[18,19] or IPAD at various pH levels.[20]

In general, to date, EC detection has not offered significant increases in sensitivity for peptide or protein analysis. However, this detection method relies on the EC behavior of the analyte rather than on its spectrophotometric activity monitored by UV or Fl detection. This could have advantages in cases where species with high spectrophotometric activity are not separated from the peptidic analyte of interest during electrophoresis or when they are encountered in the background electrolyte. Necessarily, a peptide's response to EC detection will depend on structural features different from those giving a spectrophotometric response, and thus the two methods can work in an orthogonal manner to give structural information. An example is given in Figure 2 in which comparison of PAD and 215 nm absorption detection methods indicate the presence of seven peaks which give significantly larger PAD responses relative to other peaks, owing to a higher content of specific oxidizable groups, such as oligosaccharide chains.[21] Still, the development of more applications in peptide and protein analysis has been hampered by the lack of a commercial CE system available with an EC detector. Lack of commercial development is in turn probably tied to the recent developments in MS as a powerful and informative detection system.

2.4 Mass Spectrometric Detection

Among the various direct methods of detection for peptides and proteins, MS has the potential to become one of the most important of all, certainly *the* most important when qualitative information about the identity of sample components is desired. Thus it is that much effort has been expended in developing capillary electrophoresis/mass spectrometry (CE/MS) as a ''user-friendly'' technique since the first report of the coupling of the MS to CE in 1987.[22] Since both CE and MS instrumentation have each been well developed independently, the key component is the interface. Advances in this area are to the point where commercial vendors have made CE/MS interface kits available for their instruments. For those CE instruments not designed for use with MS, there is an article which provides an experimental foundation on such interfacing with specific reference to application toward the separation of bioactive peptides and of a complex protein mixture.[23] Before examining the various modes of interfacing and their suitability for peptide and protein analysis, it should be noted that the power of MS has been utilized extensively off-line on samples collected from CE. In this procedure, the matrix-assisted laser desorption/ionization (MALDI) technique[24] of sample ionization has been utilized with great success for protein analysis. MALDI can provide good qualitative information on peptide identity but it is not a quantitative technique. Also, since it is technically not a detection technique but rather an off-line method, it will not be discussed further.

Although the potential of a variety of CE/MS ionization techniques has been explored, there appear to be two methods that have been used most often – fast atom bombardment (FAB) and electrospray ionization (ESI). An excellent chapter with references to these techniques and other interface methods has been published.[25] Of these two methods, FAB is the more difficult to implement since it requires a high vacuum for ionization whereas ESI can produce ions at atmospheric pressure. Also, ESI offers the advantage of being able to produce molecular ions with greater than one positive charge. Mass spectrometers measure the intensities of species separated according to their mass-to-charge ratio, m/z, and molecules such as large proteins, if only singly charged, would produce very high m/z ions, often beyond the range of the mass spectrometer. Multiple charges on the protein would bring the m/z values back down into the spectrometer's range. Thus, a protein of M_r 25 000 possessing 25 positive charges can be detected on a spectrometer with a 1000 m/z range. In general, the ESI interface has found widespread use in current peptide and protein applications owing to its combination of versatility, as demonstrated above for producing multiply charged ions,

Figure 2 Comparison of CE analysis using PAD *vs* UV detection of a tryptic digest of recombinant tissue plasminogen activator. Detection: (a) PAD; (b) 215 nm; (c) 280 nm. Peaks 1–7 give increased response in PAD relative to other peaks. (Reproduced from Weber and Lunte,[21] by permission of Wiley-VCH.)

facility in implementation, high mass accuracy (0.1%) and high sensitivity.[3,25]

In ESI, a high electric field is generated between the tip of the capillary and the source of the mass spectrometer, causing charged liquid droplets to form. The droplets undergo a loss of solvent, resulting in an accumulation of charge until coulombic explosion occurs. This explosive process repeats to produce ultimately analyte ions in the gas phase. Of the different types of ESI interfaces that have been developed, all can be categorized as either sheath flow or sheathless designs. Figure 3(a) and (b) depict a sheath flow design typical of commercial interfaces and a new sheathless design, respectively. The sheath flow design utilizes the coaxial flow of a liquid to maintain the electrical contact necessary for the electrophoretic process. Also, the composition of the coaxial solution can be adjusted to permit the use of CE buffers that would otherwise perform inadequately when electrosprayed. The general performance in terms of the mass spectral considerations, such as spectral quality, are similar for all designs, whether sheathed or not. The major disadvantage of the sheath flow method is that it suffers from an inherent loss of sensitivity due to the mixing of the coaxial solution with the CE effluent. This loss is due not only to analyte dilution by the incoming solution but also to ionization of solutes present in the coaxial solution. Hence there exists an interest in developing sheathless designs similar to Figure 3(b) that possess the versatility and reliability of the sheathed design.[25]

Although the use of sheath flow ESI results in a loss in sensitivity, the dilution of the CE buffer by the flow does offer some advantages in the terms of the variety of usable CE buffers. In order to be soluble, certain proteins may require relatively high salt concentrations and buffers up 0.1 M salt concentration are acceptable in ESI. Still, maximum sensitivity is obtained by using volatile buffers, such as acetic acid, formic acid or ammonium acetate, at low concentration. Unfortunately, surfactants such as sodium dodecyl sulfate (SDS) in the buffer generate intense background signals, thus limiting the use of MEKC as an electrophoretic separation mode.

The real power of CE/MS utilizing an ESI interface lies in its ability to give qualitative information about an analyte, but to what extent can that power be exploited for analysis of peptides and proteins? To answer this question, a number of different factors must be considered. These factors can be divided into (a) those characteristic of the analyte and its matrix, (b) those of the CE separation and (c) those of the MS performance in conjunction with the ESI interface.

Concerning analyte and matrix considerations, obviously any complexity in the matrix will diminish the usefulness to the extent that it interferes with the CE separation or the performance of the mass spectrometer.

Figure 3 Schematic illustration of CE/electrospray interfaces: (a) sheath flow (coaxial) and (b) exploratory sheathless design. (Reproduced from Smith et al.[25] by permission of Academic Press, Inc.)

More importantly, the higher the molecular weight of the analyte, the more complex is the structure and, thus, the greater the range of masses that must be scanned in order to provide enough information to be useful in structural determinations. That is, a larger scan range would be required for an octapeptide than a tripeptide in order to determine its amino acid sequence.

The CE separation conditions will determine, in part, characteristics of the electropherogram such as resolution and, related to resolution, peak widths at half-heights ($w_{1/2}$). Of course, two well-resolved peaks will place less demand on mass spectral performance than would be otherwise, but also important is the $w_{1/2}$ of a particular peak. Depending on the analyte, this is generally in the range 1–5 s. Peaks with low $w_{1/2}$ put a demand on the performance of the mass spectrometer by requiring a high scan rate in order to sample the peak precisely.

Currently, quadrupole MS instruments are most often used in CE/MS systems using ESI as they give the best overall performance relative to expense. The main impediment they suffer is a lack of sufficient sensitivity due to the maximum number of ions actually introduced and detected per second ($\sim 6 \times 10^7$). It has been determined that if 10 scans are required to profile adequately a peak

with a $w_{1/2}$ of 1–3 s (a scan speed of ~0.2 s) while scanning from m/z 100 to 2000 in 0.2 m/z steps, a dynamic range of only 5 would be achieved. If the scan speed is increased to 1.4 s while scanning only a range of m/z 500 in 1 m/z steps, the dynamic range increases to ~400.[26] In general, as one lengthens the scan speed while lowering the scan range and the m/z resolution, one gains in sensitivity and dynamic range. Thus, it has been stated that a scan range of a few hundred daltons at a scan speed of about 1 s is about all that can be expected with conventional instrumentation.[27] The performance is limited in part to the fact that the CE buffer ions in addition to the analyte will be ionized in the process, thus reducing the percentage of total ions in the spectrometer due to the analyte. The use of a volatile buffers will decrease their contribution to the total ion current and improve performance.

Thus, in order to introduce the needed mass (in the range from high picomoles to low femtomoles) for MS analysis one generally needs relatively high analyte concentrations (in the micromolar range). A number of general methods have been developed for concentrating samples in CE regardless of the detection method. These procedures, which include sample stacking, transient isotachophoretic focusing and using packed precolumns, have been applied successfully to peptide analysis with MS detection.[28,29]

Another simple way to increase capillary electrophoresis/electrospray ionization/mass spectrometry (CE/ESI/MS) performance is to use reduced elution speed detection (RES).[30] In this method, as exemplified in Figure 4(a) and (b), the sample mixture is electrophoresed under the usual high field strength (300 V cm^{-1}, in this case) until just before the first peak is ready to elute from the CE column. At that time, the field strength is dropped (to 30 V cm^{-1}, in this case) to allow the separated component to elute more slowly from the column. This permits more efficient ionization of the solute in the electrospray source, resulting in a greater fraction of the analyte actually sampled. This can be utilized to do one or more of the following: (a) increase the scan speed and enhance sensitivity, (b) increase the scan range, (c) increase the m/z resolution or (d) maintain the same scan speed and thus increase the number of scans for a particular peak. In the example cited, molecular weights were obtained with high precision and detection limits were lowered.

Since conventional CE/ESI/MS suffers from the restrictions listed above, it is often useful to use the system in an MS mode referred to as selective ion monitoring (SIM). This can be used when molecular weights and the m/z values likely to be generated are known and one can select a particular m/z value to monitor. The increase in sensitivity of SIM over the scanning mode is remarkable.

Figure 4 Comparison of (a) constant field strength and (b) RES in the CE/ESI/MS analysis of a mixture of four proteins. Fields strengths: (a) constant at 300 V cm^{-1}; (b) 300 V cm^{-1} until 1 min prior to elution of the first protein, when the field strength was reduced to 30 V cm^{-1}. (Reproduced from D.R. Goodlett, J.H. Wahl, H.R. Udseth, R.D. Smith, 'RES Detection for CE/MS', *J. Microcol. Sep.*, **5**(1), 57–62 (1993), Copyright 1993 John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

For a test pentapeptide, the detection limits in the low femtomole range in the scanning mode are reduced to the low attomole range.[25]

Alternative types of MS detectors are in various stages of development. One of the most promising techniques seems to be time-of-flight mass spectrometry (TOFMS), with its parallel detection and high repetition rates. A published report utilized a TOFMS system with a sheathless ESI interface to analyze test proteins, yielding low femtomole sensitivity and, more importantly, high mass resolution and accuracy (resolution greater than 6000 at 10 ppm).[27] Interestingly, the amount of data generated by such detection systems is often beyond the storage and software capabilities of the computer systems used and only selected data acquired are actually recorded.[31]

In terms of actual applications to peptide and protein analysis, CE/MS has been used primarily for the examination of standards[32] and not ''real-world'' samples.[28] A review indicated that 29 different peptides have been

analyzed by various researchers using CE/MS. While 27 of these were studied using a system with an ESI interface, only 12 used a FAB design.[28] The same review also indicated that 21 kinds of proteins have also been examined by CE/MS. The majority of these were ''developmental'' studies not designed to answer biological or protein-synthesis problems. Examples of some of the exceptions include the use of CE/MS to determine protein purity. In one example, impurities in a preparation of a synthetic monoclonal antibody against herpes virus were detected.[33] An example of a biological application can be found in the analysis of protein fragments in urine by on-line preconcentration followed by CE/MS.[34]

One of the most promising areas of CE/MS application is that of peptide mapping and sequencing. Protein digests usually contain a large number of different peptide fragments as a result of proteolytic action. The high separating efficiency of CE affords good separation of the fragments while the power of MS lies in its ability to identify separated fragments. The electropherograms shown in Figure 5(a) and (b) are instructive in that both UV and MS detection were used in this analysis of a tryptic digest of tuna cytochrome[35] and, as expected, the general profiles of both electropherograms are similar. As discussed earlier, the relatively high-molecular-weight fragments were doubly charged and fell within the m/z range of the mass spectrometer, which can be used to identify peaks. Generally, most fragments detectable by UV absorption are observed by MS. Exceptions may be small entities such as amino acids and dipeptides owing to the difficulty in operating MS over a wide m/z range.[25] It should be noted that the equipment used to obtain the results in Figure 5(a) and (b) was a commercial CE system that had been modified to allow UV detection at half the MS detection time. Since the time of this publication, commercial equipment has become available that permits simultaneous UV/VIS and MS detection.

Newer developments in the CE/MS analysis of protein digest have focused on aspects necessary in identifying components in small amounts of sample. One thrust of this effort is to develop CE capabilities to not only provide molecular weight values for the peptides in a CE peptide map, but also to sequence peptides by tandem mass spectrometry (MS/MS). A second aim is to be able to apply these techniques to the relatively low concentrations often encountered in analysis. A good example of the current research directed towards these ends is found in a report detailing the use of a solid-phase extraction (SPE) device coupled to a CE system which, in turn, was coupled to a triple quadrupole mass spectrometer and operated in the SIM mode.[36] SPE led to picomolar detection limits while MS/MS analysis permitted the identification of peptides containing 9–20 amino acid residues. The procedure was

Figure 5 Comparison of (a) UV absorbance (214 nm) detection and (b) MS reconstructed ion electropherograms, with time axes adjusted for corresponding peaks, for a CE/MS separation of a tryptic digest of tuna cytochrome c. (Reproduced from Smith et al.[25] by permission of Academic Press, Inc.)

applied successfully to the analysis of minute amounts of peptides that had been separated and isolated by slab gel electrophoresis. The enthusiasm and optimism of researchers in the field is evident in the following quotation: ''It appears that continued development in the chemical and instrumental aspects of capillary electrophoresis/tandem mass spectrometry (CE/MS/MS) will push this technique to the forefront of the field of bioanalytical chemistry.''[3]

Other research in the CE/MS area has focused on the development of alternative MS detection systems. Alternative detection systems can give superior performance but the systems are not readily available, may be difficult to interface, and are often expensive. Also

explored has been the application of MS detection to modes of CE other than conventional CZE. Since capillary isotachophoresis (CITP) can accommodate much larger sample volumes than CZE and, in addition, analyte bands are concentrated during separation, improvement in concentration detection limits over CZE should be possible. CITP has been coupled to MS and applied to the analysis of proteins,[37] but subsequent reports using the method have been sparse. MEKC coupled to MS would normally be prohibitive owing to interference of the surfactant, but one application used the method for the analysis of peptides by causing analytes to migrate through a micellar solution for separation and then into buffer containing no surfactant before entry into the mass spectrometer.[38] Coupling CIEF to MS has also been accomplished and applied to separations of hemoglobin variants differing in p*I* by ~0.05 pH unit.[39]

Overall, developments in MS detection systems have been proceeding at rapid pace and resources such as the biannual reviews on CE and MS that appear in June 15th issues of *Analytical Chemistry* are a helpful tool to help keep abreast of the field. One general trend that is evident is advancement of microscale MS detection methods. Various research groups are utilizing microfabricated devices for CE/MS with an ESI interface[40,41] and evaluating the performance of such systems for biomolecule analysis.[42] Microchip devices will be an important part of analytical instrumentation of the future and the high informational content available through MS detection would certainly make such systems extremely useful.

3 FLUORESCENCE DETECTION METHODS FOR DERIVATIZED SAMPLES

For the sensitive analysis of peptides and proteins using relatively affordable, commercially available equipment, derivatization of the analyte with a fluorophore and use of Fl detection, particularly laser-induced fluorescence (LIF), is the current method of choice. Sensitivity enhancements over UV absorbance detection are typically two to three orders of magnitude, with concentration detection limits usually in the low-nanomolar range. However, the method is not without its own problems.

Since Fl detection had seen widespread use in liquid chromatography (LC) prior to the advent of CE, a variety of derivatizing reagents for the introduction of the fluorophore have been developed for LC and are useful for CE analysis. Since the introduction of CE, new reagents have been introduced and often find applications in both LC and CE. Indeed, an extensive review of labeling reactions for small amounts of protein in CE and LC analysis has appeared,[43] while another review has focused on derivatization in CE of all types of analytes, not just peptides and proteins.[44]

Some of the more widely used derivatizing agents in CE are given in Table 1. No one reagent can be said to be the best for use in all situations, for a variety of reasons. An initial consideration would be the type of analyte.[43] Large proteins contain multiple sites for a tagging reaction while a small peptide may contain few. From a cursory examination of Table 1, one can see that most reagents are designed to react with amino groups of the peptide or protein. If such a reagent is used with a large protein, multiple amino groups may be labeled, depending on the reaction conditions, while a small peptide may be singly labeled owing to the presence of only one available reaction site. The problem with having many potential labeling sites is that not all sites may react to the same extent, thus introducing greater heterogeneity into the analysis. Large variations in reactivity within proteins are a very real concern since each of the sites exists in a microenvironment with distinct reactivities such as the nucleophilicities of amino groups. Labeling of undesired sites, such as the cross-reactivity of thiols with amine

Table 1 Properties of fluorescent derivatization reagents for peptide and protein analysis by CE

Derivatization reagent	Abbreviation	$\lambda_{ex}/\lambda_{em}$ (nm)	Reacts with	Ref.
4-Phenylspiro[furan-2(3*H*), 1-phthalan]-3,3-dione	Fluorescamine	390/450	Primary amines	46, 52
Fluorescein isothiocyanate	FITC	494/525	Primary and secondary amines	46
9-Fluorenylmethyl chloroformate	FMOC	260/305	Primary and secondary amines	46
o-Phthalaldehyde	OPA	340/450	Primary amines	46, 52, 53
3-(4-Carboxybenzoyl)-2-quinoline carboxaldehyde	CBQCA	442/550	Primary amines	47
Naphthalene-2,3-dicarboxaldehyde	NDA	440/490	Primary amines	48, 54, 55
4-Chloro-7-nitrobenzofuran	NBD-Cl	468/540	Primary and secondary amines	45
Tetramethylrhodamine-5-isothiocyanate	TRITC	548/578	Primary and secondary amines	50
Benzoin	–	325/440	Arginine-containing peptides	49
4-Methoxy-1,2-phenylenediamine	–	330/438	Tyrosine-containing peptides	49

labeling reagents, is also a problem. One might consider adjusting the reaction conditions so that only one reactive site per protein or peptide molecule is labeled but, even if this could be achieved, the relatively small number of labels per molecule would result in low sensitivities, which defeats the purpose of labeling. Hence complete labeling of all desired functionalities is usually the goal of derivatization but can be difficult to achieve, especially for large proteins. In general, the reagents listed in Table 1 are more useful for small peptides than large proteins.

If heterogeneity results from labeling, then separation modes and conditions must be used to cause co-migration of a heterogeneously labeled analyte. An example of such a situation is found in a report in which four proteins of M_r 20 000–77 000 were fluorescently labeled and then separated by SDS capillary gel electrophoresis.[45] CE of labeled proteins exhibited the same separation efficiencies as for unlabeled analytes whereas the limits of detection were enhanced 20-fold over UV absorbance detection. In general, a derivatizing agent should not adversely affect the separation properties of the analytes, a requirement which is perhaps not too difficult to achieve for small peptides which are singly labeled but represents a challenge for large proteins.

Of course, it is also desirable to have a labeling reagent which reacts quickly in an efficient manner while producing a high yield of tagged analyte. These are general features one looks for in any reaction, but they can be particularly important in labeling reactions, especially when postcolumn derivatization is used. Most derivatization procedures are applied prior to injection in an off-line mode for convenience. This is often acceptable as long as one is careful to avoid excessive dilution of the sample with reagent, which diminishes the increase in sensitivity that one is striving for. Table 1 lists examples of a number of useful reagents. Precolumn derivatizations of peptides for CE analysis have been accomplished using some of the ''classical reagents'' such as fluorescamine, fluorescein isothiocyanate (FITC), 9-fluorenylmethyl chloroformate (FMOC) and *o*-phthalaldehyde (OPA).[46] Unfortunately, some of these reagents do not exhibit an excitation maximum coherent with the wavelength of common, commercial lasers such as the He–Cd or Ar-ion lasers and thus exhibit diminished Fl with such sources, resulting in decreased sensitivity. The development of specific reagents, such as 3-(4-carboxybenzoyl)-2-quinoline carboxaldehyde (CBQCA), with an excitation maximum close to the 442 nm light of commercial He–Cd laser, has been realized and applied to the detection of peptides.[47] Prior to the advent of CBQCA, naphthalene-2,3-dicarboxaldehyde (NDA) had been used to generate tagged peptides with a similar excitation maximum, and it has seen widespread use, including the analysis of single vesicles from a gastropod mollusk.[48] Its popularity stems in part from the fact that the reagent is not inherently fluorescent but rather fluorogenic. Thus, unreacted reagent will not interfere in the Fl detection of an analyte. Indeed, such interferences can make reagents such as FITC, which contains a fluorescent fluorescein group, unsuitable for protein analysis even though the labeled protein would have an excitation maximum near 448 nm, the output from commercial Ar-ion lasers. However, this laser's light is close in wavelength to the excitation maximum of analytes tagged with 4-chloro-7-nitrobenzofuran (NBD-Cl) and proteins so labeled have been used for molecular mass studies.[45] Certain reagents have been developed to react with functionalities other than amino groups. These include benzoin, which labels arginine, and 4-methoxy-1,2-phenylenediamine which labels formylated tyrosine.[49] An application of precolumn derivatization utilized tetramethylrhodamine-5-isothiocyanate (TRITC) to label an enkephalin in rat serum with detection limits in the low attomole range, suggesting that capillary electrophoresis/laser-induced fluorescence (CE/LIF) may be useful in the analysis of therapeutic peptides in physiological matrices.[50]

While peptides can be fluorescently labeled by on-column derivatization,[51] the method has seen little use since some of the reagents are present in the background electrolyte. Additionally, conditions must be optimized concurrently for derivatization of the analyte and the separation by CE. However, postcolumn on-line derivatization of peptides is an active area of research that offers some significant advantages over precolumn derivatization. There are fewer manipulations of the sample prior to injection, facilitating the ease with which the sample is analyzed. Also, a peak due to labeling reagent will not be present to hide analyte peaks. Most importantly, peptides are separated by their inherent electrophoretic mobilities unencumbered by the fluorescent tag and the anomalies this may produce, such as the previously discussed heterogeneity of multiply tagged proteins. Reaction kinetics must be fast, resulting in a restriction on the variety of useful reagents. The most popular reagents for this purpose are fluorescamine,[46,52] OPA[52,53] and NDA.[54,55] Detection levels in the high nanomolar range were obtained in the analysis of neuropeptides and proteins using NDA,[54] while another method used fluorescamine to attain detection limits below nanomolar levels and the method was applied to the analysis of tryptic digests.[52] An interesting application of this postcolumn derivatization method used NDA and β-mercaptoethanol to label the physiologically important peptide substance P (SP) and its metabolites.[55] In this study, microdialysis samples were obtained periodically after perfusion of rat striatum with SP and subjected to

Figure 6 Electropherograms of microdialysis samples obtained after perfusion of rat striatum with 300 μM SP at 0.3 μL min^{-1}. (Reproduced from K.L. Kostel, S.M. Lunte, 'Evaluation of Capillary Electrophoresis with Post-column Derivatization and LIF Detection for the Determination of Substance P and Its Metabolites', *J. Chromatogr., B: Biomed. Appl.*, **695**(1), 27–38 (1997), Copyright 1997, with permission from Elsevier Science.)

CE/LIF analysis to generate the electropherograms in Figure 6.

A variation of postcolumn derivatization that enhances the specificity of the fluorescent tag is found in the use of an affinity-labeling technique. In this method, a fluorophore is bonded to a protein which will form an immune complex with the protein to be analyzed. One recent example of this system employs fluorescein-labeled fragment B of protein A to detect human IgG FC variants.[56]

Overall, off-line precolumn derivatization is most commonly used but no reagent meets the ideal of selectively tagging an analyte at trace levels in an efficient, homogeneous manner. The matter is further exacerbated when analytes are found in complex matrices such as serum or urine. Although on-line precolumn tagging in CE has not been developed, on-line postcolumn methods seem promising, but the lack of commercially available systems has slowed application developments.

4 OTHER DETECTION METHODS

Peptides and proteins can be detected using other methods but reports using these techniques are rather isolated and have not been developed. These include the use of indirect detection in which a fluorescent species is added to the separation buffer and the analytes generate negative peaks as they displace the fluorophore. Although some increase in sensitivity over UV absorbance detection is gained in protein analysis using this method,[57] it suffers from difficulties encountered in quantitation and also from the fact the method is non-selective. Another universal detection method applied to protein studies is thermo-optical absorbance (TOA) detection.[58] In TOA, absorption of incident laser light by an analyte causes a temperature rise in the surrounding solution. A probe beam monitors this solution and changes in intensity proportional to analyte levels. This technique, though technically demanding, exhibits sensitivity similar to that

of LIF. Chemiluminescence has also been used for peptide detection in a peroxide–luminol-based system. As peptides bind to Cu^{2+} in the system, the ability of the copper to catalyze the reaction is diminished and less light is generated. This indirect method provides a rather limited method of analysis.[59]

The use of a biological system, such as a cell, as a detection method has also been introduced. Bradykinin peptides were separated by CE and the effluent containing the peptides was allowed to pass over the surface of cells containing receptors for the bradykinins. Binding to receptors caused release of Ca^{2+} which, in turn, caused an increase in the Fl of Fluo-3-AM, a calcium indicator.[60]

5 COMPARISON OF DETECTION METHODS

In summary, there are a variety of CE detection modes for peptides and proteins and the suitability of any one method for a particular application depends on the conditions both of the sample itself and, when considering the cost of the method, the facility performing the analysis. For applications where sensitivity is not of paramount importance, that is, the analyte is found in concentrations in the micromolar range, UV absorbance detection is well suited to the task. It is robust, straightforward and relatively inexpensive. With minimal increase in expenses, a diode-array or multiwavelength version can yield useful information for identification purposes. It should be noted that preconcentration of a sample either off-line or on-line can effectively increase the ability to analyze lower concentrations to some extent.

EC detection is a method orthogonal to UV absorbance detection since it relies on the EC activity of the analyte. It has not been shown to be significantly more sensitive than UV detection but could offer a mode that may be less expensive than UV detection if commercialized. Miniaturization of this mode is being explored and EC detection may find its real future in microscale applications.

For CE analysis of peptides at nanomolar levels, derivatization with a fluorophore and LIF detection is usually recommended. The manipulations involved and the need for reaction efficiency can be concerns, but a variety of reagents exist which often suit the task. Use of this method on large proteins can be difficult, however, owing to problems arising from multiple, potential reaction sites.

Finally, MS detection may be the ideal detector in terms of the quality of information provided for peptide and protein analysis, particularly in the area of peptide mapping. However, the method is not a ''mature'' one. In the scanning mode, the sensitivity is lower than for LIF of derivatized samples and, at normal scanning rates, the scanning range is limited. Considering the relatively high expense of the system and the need for the user to interface the CE and MS units, perhaps with a commercial interface, one must consider carefully the value of such a detection method. Still, there is probably more method development occurring in this area of CE detection than in any other. Perhaps in the future, commercial CE/MS systems analogous to the ubiquitous gas chromatography/mass spectrometry (GC/MS) units may be found as part of the instrumentation in laboratories performing peptide and protein analysis.

The ability to resolve effectively peptides obtained by chemical or proteolytic cleavage is important in the structural investigation of proteins, whether it be minute amounts of protein isolated from a biological source or protein produced recombinantly for pharmaceutical use. Capillary electrophoresis (CE) can be used rapidly to resolve peptides electrophoretically in free solution with a selectivity that differs from that of other separation approaches. In this article, we provide a description of the instrumentation for CE and the fundamental principles driving peptide separation at low and high pH. Guidelines for method optimization of peptide injection and separation by CE are given along with a number of examples from the literature demonstrating the utility of CE for interrogating protein structure via CE-based peptide and glycopeptide analysis.

1 INTRODUCTION

Electrophoresis in capillaries (CE) has gained popularity as a separation technique applicable to both low molecular mass and macromolecular analytes.[1] Separation in low ionic strength buffer is primarily due to differences in analyte charge-to-size ratio. The inability to separate neutral or uncharged analytes by capillary zone electrophoresis (CZE), where they migrate at the electroosmotic boundary, led to the development of micellar capillary electrophoresis (MCE) by Terabe et al.[2] With this mode, an appropriate micelle-forming detergent is added to the separation medium, and separation of the analytes occurs as a result of both electrophoretic mobility (due to charge/mass) and chromatography (due to partitioning of the analyte into the micelles through hydrophobic interaction). Capillary isoelectric focusing (CIEF) involves filling a coated capillary [to eliminate or severely reduce electroosmotic flow (EOF)] with ampholines in an appropriate buffer, injecting the sample, focusing the analytes for a short time, and then mobilizing the focused analyte zones past the detector. This can be accomplished utilizing either a change in electrolyte media to effect EOF or by alteration of hydrostatic pressure; most commercial instruments allow the use of a combination of the two mobilization techniques.[3] While capillary isotachophoresis (CITP) is a separate analytical mode of CE and one of the first to be explored in CE, it is currently used mostly as an on-capillary preconcentration technique.[4] Finally, capillary gel electrophoresis (CGE) effects separation in either an immobilized polymerized matrix within the capillary (e.g. polyacrylamide) or in a free-flowing sieving matrix (e.g. methylcellulose).[5] Sieving matrices are necessary with analytes, such as sodium dodecyl sulfate (SDS)–protein complexes or DNA, where the charge-to-mass ratio is identical regardless of size; here the separation is proportional to size. The primary modes used for the separation of peptides are CZE and MCE, although CIEF and CITP have their potential for specialized applications. CGE could be used for small SDS–peptide complexes with the appropriate matrix.

1.1 Instrumentation

A generalized configuration for CE instrumentation is given in Figure 1. With CZE, sample is introduced into

Figure 1 General configuration for CE instrumentation.

Figure 2 Deprotonated silanols on the capillary surface generate an EOF. (a) A fused-silica capillary has a negative surface charge in most pH ranges, resulting in the formation of a positive double ion layer (and hence a ζ potential) at the surface. Under normal polarity (inlet, anode; outlet, cathode), the positively charged ions will migrate toward the outlet inducing an EOF towards the detector. (b) If the surface is coated with a nonionic layer, no surface charge (ζ potential) will be established and, therefore, there is no EOF. Because there is reduced or no EOF, the electrode polarity must be chosen appropriately so that the molecules of interest have the opposite charge to the outlet electrode. (c) Capillary coatings imparting a positive charge to the inner capillary surface will attract a layer of negative ions. Here the EOF will be anodic in direction.

a buffer-filled capillary either electrokinetically (with low voltage) or hydrodynamically (with pressure or vacuum). Both ends of the capillary are then placed into buffer solution that also contains the electrodes and a high voltage applied to the system. As a result of the applied voltage, the analytes migrate through the capillary and past a detector window where information is collected and stored by an appropriate data acquisition system. Two electrically driven phenomena contribute to the mobility of the analyte: electrophoretic mobility of the analyte and EOF of bulk solution. The charged analyte is mobilized electrophoretically in a manner that is a function of its charge and size, but is also carried by the net movement of buffer toward the cathode due to EOF. EOF is the result of the negative charge imparted to the inner surface of the capillary by the bare silica where cations form an organized double layer along the wall. Under an applied field, the double layer is propelled along the wall in the direction of the cathode. Unless altered through the addition of buffer additives, the use of a coated capillary or with low-pH buffers, the EOF is usually adequate to force the movement of all molecules toward the cathode and past the detector (Figure 2). This includes those with a net negative charge which are electrophoretically drawn toward the anode [assuming a polarity of (anode) → detector → (cathode)]. Subsequently, the analyte order in any given electropherogram has the fastest migrating species passing the detector window first and the slowest passing last (i.e. peaks from left to right represent the fastest to slowest migration). The capillary used for electrophoresis is made from fused silica and typically has an inner diameter in the range 20–200 μm (outer diameter of 200 or 375 μm) and an effective length of 7–100 cm. An external coating of polyimide makes a narrow-bore capillary surprisingly flexible.

1.2 Detection

There exist a number of on-line detection modes for CE, many of which have been developed based on high-performance liquid chromatography (HPLC) detection systems. These include ultraviolet/visible (UV/VIS) absorbance, fluorescence and conductivity. With some instrumentation, diode-array detection capabilities provide additional information. The absorbance spectra obtained through the use of scanning diode-array detection are often useful for component identification; however, sensitivity is somewhat compromised. Mass spectrometry (MS) shows promise as a versatile, powerful and sensitive detector for certain CE separations.[4] There are defined limitations associated with the use of MS as a CE detector when interfaced via electrospray; however, low-pH separations in low ionic strength buffers are easily accomplished and very useful for peptide analysis.

1.3 Modes

Similar to the diversity associated with both conventional gel electrophoresis and HPLC, several modes of CE have been developed. The family of specialized techniques that

have resulted include CZE, MCE, CIEF and CGE. Of these, only CZE and MCE are pertinent to a discussion of CE of peptides. CZE, the most common CE technique, is utilized for both low molecular mass analytes and macromolecules. In contrast to conventional slab gels, separation using CZE is performed in free solution. This means that a gel matrix support is not required, although one can be implemented if desired. A necessity for CZE is that the analytes must be charged or chargeable as separation is achieved based on the species mass-to-charge ratio. CZE may be a misnomer because it implies that CZE is the only CE technique in which the solute forms a zone and migrates at constant velocity. However, CGE is also a zonal technique; thus, CZE is often referred to as free solution CE.

The inability to separate neutral or uncharged analytes with CZE led Terabe's group[6] to develop MCE.[7] The use of an appropriate micelle-forming detergent in the separation buffer allows for separation to occur based on both electrophoretic mobility (due to charge) and partitioning of the solutes into the micelles. While this technique has mainly been exploited for the analysis of small, hydrophobic solutes, it has some applications in the analysis of peptides.

1.4 Introducing Peptides into the Capillary

As a result of the small dimensions of capillaries used in CE, the total capillary volume is typically in the microliter range. For example, a 47 cm × 50 μm capillary has a total capillary volume of 920 nl. Adhering to a commonly accepted ''rule of thumb'' restricting the injected sample volume to ~1% of the total capillary volume, sample volumes are limited to the nanoliter range to avoid overloading.[8] The small sample volume injection into a capillary is usually accomplished by one of three methods. With hydrostatic injection, sample is introduced by pressurizing the inlet vial containing the sample or applying a vacuum to the outlet vial (opposite end) while immersing the capillary inlet into a vial containing the sample. Although much less common, sample introduction can also be accomplished through siphoning, which relies on gravity to introduce the sample into the capillary. Elevation of the inlet end of the capillary to a predetermined height while positioned in the sample vial allows for reasonably accurate delivery of the sample into the capillary and is used routinely with noncommercial (home-made) instruments.

With electrokinetic injection, the most popular method of sample introduction for peptides, the inlet is immersed in the sample and the outlet end placed in the separation buffer with a low voltage (1–10 kV) applied for a short period (usually several seconds) while the sample peptides migrate electrophoretically into the capillary. With peptides, one must be aware of the dependence of analyte injection on a number of parameters. One of the most important is the electrophoretic mobility of the sample components as they migrate into the capillary, in combination with the magnitude and direction of the EOF (the ''bulk'' flow though the capillary when current is applied). Other parameters which can effect this mode of loading include the sample buffer (particularly the ionic strength and pH) and the composition of the sample matrix. The strict dependence of this injection mode on electrophoretic mobility ''biases'' sample introduction; sample components with the highest electrophoretic mobility will be preferentially introduced over those with lower mobilities. Therefore, the results obtained with electrokinetic loading may not be a quantitative representation of the sample peptides. However, electrokinetic loading may be advantageous if the analyte of interest is only a small percentage of the total sample but has a much higher electrophoretic mobility than other constituents. Because of the unique charge characteristics of proteins and peptides (i.e. the presence of charged residues), the charge of the peptides of interest can be manipulated by conditions of pH to enhance their electrophoretic mobilities and provide a positive sample loading bias that may enhance detection by virtue of the selective injection of peptides and proteins preferentially over uncharged sample species. Another situation where electrokinetic introduction is advantageous involves electrophoretic separation in the presence of a polymerized or cross-linked matrix, where pressure injection cannot be used without physically damaging the separation matrix (e.g. SDS–protein complexes separated in a gel-filled capillary). It is noteworthy that sample matrices containing significant concentrations of electrolyte or salts are not efficiently electrokinetically introduced and must be either diluted or desalted before injection.

1.5 Electrophoresis-based Capillary Sample Concentration Techniques

One of the main drawbacks of ultraviolet (UV) detection in CE is the low sensitivity resulting from the inherently small dimensions of the flow cell (most commonly the inner diameter of the capillary) and the injected sample volume. As mentioned previously, introduction of sample volumes substantially larger than ~1% of the total capillary volume can result in poor resolution. While CE is a good mass detector, its poor performance as a concentration detector severely limits its use as an analytical technique to samples having nominally high concentrations (10 $\mu g\,mL^{-1}$ or greater). For this reason, the development of several approaches for ''on-capillary sample concentration'' have been pivotal to the acceptance of CE as a microanalytical technique. These

techniques are only briefly discussed here but may be investigated in greater detail from other sources.[9]

1.5.1 Sample Stacking

One of the simplest methods for sample preconcentration is to induce sample ''stacking'' in a manner comparable to that developed by Hjerten for slab gels.[10] This is easily accomplished in CE by exploiting ionic strength differences between the sample matrix and separation buffer.[11] Sample components in an environment lower in ionic strength than the separation buffer experience an amplified field (and an enhanced electrophoretic mobility) and accelerate to the sample/separation buffer interface where they are slowed by the higher ionic strength of the separation buffer. Within a short time, the ionic strength gradient dissipates and the charged analyte molecules begin to move from the ''stacked'' sample zone toward the cathode. The subsequent reduction in the length of the sample zone as a result of ''stacking'' is roughly estimated to be the ratio of the ionic strength of separation buffer and sample matrix. Stacking can be utilized with either hydrostatic or electrokinetic injection and can typically yield a 10-fold enhancement in sample concentration and, hence, sensitivity (Figure 3). When possible, dissolving the sample in dilute separation buffer may be more advisable than in water since the dramatic differences in EOF between the sample plug and separation buffer may cause laminar flow within the capillary and, hence, lead to peak broadening.[13–16] Since excessive heat produced in the sample plug may denature sample components,[17–19] it may be advisable to ''stack'' at lower applied voltages or ''ramp'' to the separation voltage over several minutes.

Figure 3 Field amplified stacking of peptides. Separation of a standard peptide mixture (peptide calibration kit, Bio-Rad, Richmond, CA, USA) in a phosphate buffer (pH 2.5) sample matrix at varying concentrations: bottom, 50 mM; middle, 5 mM; top, 100 mM. Separation conditions: 5 s hydrostatic injection; 10 kV running voltage; 50 μm × 27 cm (20 cm to detector) capillary. Peaks: 1 = bradykinin; 2 = angiotensin; 3 = α-melanin-stimulating hormone; 4 = thyrotropin-releasing hormone; 5 = luteinizing hormone-releasing hormone; 6 = leucine enkephalin; 50 μg mL^{-1} each. Separation buffer was 50 mM phosphate buffer (pH 2.5). (Reproduced by permission from Castognola et al.[12])

1.5.2 Sample Focusing

An alternative approach identified for on-capillary stacking is sample ''focusing'' and is based on pH differences between the sample plug and separation buffer. This has been shown to be very useful for the analysis of peptides, mainly owing to their relative stability over a wide pH range.[8] Focusing is accomplished by altering the pH of the sample to a point above the net sample pI (isoelectric point). The high-pH sample plug is flanked between low-pH separation buffer zones (i.e. an equivalent volume of low-pH separation buffer following introduction of the sample plug) and, upon applying a voltage, the negatively charged peptides in the initial sample zone migrate toward the anode. Upon entering the lower pH separation buffer, a pH-induced change in their charge state causes a reversal in the direction of mobility resulting in a ''focusing'' of the peptides at the interface of the sample (high pH) and low-pH buffer plugs. After the pH gradient has dissipated, the peptides, again positively charged in a low-pH separation buffer, migrate toward the cathode as a sharp zone. This approach, limited to samples that can withstand the inherent changes in pH without substantial denaturation, may yield as much as a fivefold enhancement in sample concentration and, hence, sensitivity. Other approaches, including isotachophoresis (ITP) sample enrichment,[20] have been utilized successfully for peptide analysis and will not be discussed here.

2 THEORY OF ELECTROPHORESIS

2.1 Mobility of the Analyte

The electrophoretic mobility (μ) of a charged molecular species can be approximated from the Debye–Hückel–Henry theory (Equation 1):

$$\mu = \frac{q}{6\pi\eta r} \tag{1}$$

where q is the charge on the particle, η is the viscosity of the medium and r is the Stokes radius of the particle. The mass of the particle may be related to the Stokes radius by $M = (4/3)\pi r^3 V$, where V is the partial specific volume of the solute. While one might infer the direct proportionality of mass and radius of the particle, empirical data suggest modifications of Equation (1) to allow for the nonspherical shape, the counter-ion effects and nonideal behavior of proteins and biological molecules.[21]

2.2 Resolution

The simplest way to characterize the separation of two components is to divide the difference in migration distance by the average peak width to obtain the resolution (*Res*) (Equation 2):

$$Res = \frac{2(x_{i2} - x_{i1})}{w_1 + w_2} \tag{2}$$

where x_i is the migration distance of analyte i, the subscript 2 denotes the slower moving component and w is the width of the peak at the baseline.[22] The position of a peak, x_i, is determined by its electrophoretic mobility. The peak width, w, is determined by diffusion and other dispersive phenomena (see below). For two neighboring peaks, $w_1 \simeq w_2$, and (Equation 3):

$$Res = \frac{x_{i2} - x_{i1}}{w_2} \tag{3}$$

from the equation describing a Gaussian curve, the two peaks touch at the baseline when $\Delta x_i = w_2 = 4\sigma$, and $Res = 1$, or (Equation 4):

$$Res = \frac{\Delta x_i}{4\sigma} \tag{4}$$

Substituting for distance ($x_i = v_i t$) and $\sigma = (2D_i t)^{1/2}$ (the width of a Gaussian curve, the theoretical shape of the analyte plug) in Equation (4), we obtain Equation (5):

$$Res = \frac{(\Delta\mu_{app} E)t}{4(2D_{i,avg}t)^{1/2}} \tag{5}$$

where $\Delta\mu_{app}$ is the difference in apparent electrophoretic mobility of the two solutes and $D_{i,avg}$ is the average diffusion of the two solutes.

2.3 Efficiency

Probability theory allows us to assess the efficiency of the transport process.[23] For a random walk process of length L, made of n steps, the variance is given by Equation (6):

$$\sigma = l(n)^{1/2} \tag{6}$$

where l is the length of each step. If each step is independent of any other step, each contributes to the total variance of the process[24] (Equation 7):

$$\sigma_{tot}^2 = \sum \sigma_i^2 \tag{7}$$

Substituting from Equation (6) and rearranging, we obtain Equation (8):

$$\frac{1}{n} = \frac{L^2}{\sigma_{tot}^2} = N \tag{8}$$

The number of steps in the random process, n, is inversely related to the number of theoretical plates, N, a measure of the efficiency of the process.

We may substitute for L and σ in Equation (8) (as we did in Equation 5) to give Equation (9):

$$N = \frac{(\mu_{avg} E)^2 t^2}{2D_i t} \tag{9}$$

where μ_{avg} is the average mobility of the two solutes. Comparing the expression for *Res* (Equation 5) with that for N (Equation 9), we may combine the two to obtain an expression relating resolution to the number of theoretical plates (Equation 10):

$$Res = \left(\frac{1}{4}\right)\left(\frac{\Delta\mu_{app}}{\mu_{avg}}\right) N^{1/2} \tag{10}$$

Equation (10) permits one to assess independently the two factors which affect resolution: selectivity, reflected in the difference of the mobility of the analyte(s); and efficiency, indicated by N.

If $Res = 1$, then (Equation 11)

$$N = \frac{16}{(\Delta\mu_{app}/\mu_{avg})^2} \tag{11}$$

Another expression for N may be derived from Equation (8), using the width at half-height of a Gaussian peak (Equation 12):

$$N = 5.54\left(\frac{L}{w_{1/2}}\right)^2 \tag{12}$$

where $5.54 = 8\ln 2$ and $w_{1/2}$ is the peak width at half-height.[25]

Note that it is misleading to discuss theoretical plates in electrophoresis. The concept comes from chromatographic theory, where a true partition equilibrium between a mobile solute and a stationary phase is the physical basis of separation. In electrophoresis, separation of the components of a mixture is determined by their relative mobilities in the applied electric field, which is a function of their charge, size and shape. The theoretical plate is merely a convenient concept to describe the analyte peak shape and to assess the factors which affect separation.

2.4 Sources of Variance

While N is a useful concept to compare the efficiency of separation among columns, or between laboratories, it refers to the behavior of a single component during the separation process, and hence is unsuited for describing the separation of two components or the resolving power of a capillary. A more useful parameter is the height equivalent to a theoretical plate (HETP)[23] (Equation 13):

$$\text{HETP} = \frac{L}{N} = \frac{\sigma_{\text{tot}}^2}{L} \tag{13}$$

HETP might be thought of as the fraction of the capillary volume occupied by the analyte. It is more practical to measure HETP as an index of separation efficiency, rather than N, as the individual components which contribute to HETP may be individually evaluated and combined to determine an overall value. The variance of multiple dispersive phenomena on the analyte may be summed (Equation 14):

$$\sigma_{\text{tot}}^2 = \sigma_{\text{diff}}^2 + \sigma_T^2 + \sigma_{\text{int}}^2 + \sigma_{\text{wall}}^2 \tag{14}$$

Ideally, electrophoresis in a noninteracting medium should result in symmetrical zones of analytes. The length of time for separation would be determined by the differences in mobility of the two analytes and thus, in theory, given a long enough separation time, one should be able to resolve any two analytes. However, in the real world, materials do not behave ideally, and analytes frequently interact with the capillary or components of the separation medium. Therefore, we must consider the sources that create nonideal behavior.

A consideration of all the factors influencing σ_{tot}^2 includes not only diffusion, but also differences in mobility or diffusion caused by Joule heating (i.e. thermal gradients generated within the capillary during the electrophoretic process), the fact that the sample is not introduced as an infinitely thin disk but as a plug of finite length, and interaction of analytes (which may not be the analyte of interest, but might affect electrophoretic mobility of the analyte of interest) with the capillary wall. While important in understanding separation in CE, this will not be discussed here and the reader is referred to literature which addresses this issue in detail.[13,26–30]

3 APPLICATIONS

3.1 Predicted Separation: Simulated Versus Observed Migration

Two approaches have been used to evaluate the relationship between electrophoretic mobility and peptide charge and mass. The first modifies Equation (1) to Equation (15):

$$\mu = kqM^{-x} \tag{15}$$

where $x = 1/3$ assuming the spherical shape of Stokes law, $x = 1/2$ assuming the shape is related to the radius of gyration and proportional to the length of the peptide chain or $x = 2/3$ assuming the frictional forces are proportional to the surface area of the peptide.

Offord[31] first proposed $x = 2/3$ based on studies of a large number of peptides by paper electrophoresis; this value has since been experimentally verified by numerous studies. Nyberg et al.[32] found a good correlation with Offord's model for a series of synthetic substance P (SP) peptides. Likewise, Deyl et al.[33,34] found a linear relationship between the mobility of cyanogen bromide fragments of collagen between pH 6.9 and 10.5 and $M^{-2/3}$, surmising that the effect of molecular size was smaller than the effect of charge, at least for small- to medium-sized peptides.

A comparison of the three models was carried out by Rickard et al.[21] using the mobilities of 33 peptides obtained at pH 2.35 and 8.15. The strongest correlation for peptides derived from the tryptic digestion of human growth hormone was with $x = 2/3$. In a study of 35 peptides with buffers at pH 2.0, 4.0, 7.0 and 10.0, Kurosu et al.[35] found the best correlation with low-pH buffers and Offord's parameter. Landers et al.[36] obtained similar results for two peptides and their homo- and heterodimers using peptide migration time (proportional to μ^{-1}), and Florance et al.[37] arrived at a similar conclusion for motilin peptides at acidic, neutral or basic pH. Offord's model has been substantiated by van de Goor et al.[38] for modified adrenocorticotropic hormone peptides over a wide pH range and by Adamson and Reynolds[39] with casein phosphopeptides.

A second, more empirical approach to define the relationship between electrophoretic mobility and peptide charge and mass was proposed by Grossman et al.[40] Using the data from 40 peptides, ranging in length from 3 to 39 amino acids and in charge from 0.33 to 13, they fitted their mobility data to Equation (16):

$$\mu = \frac{k_1[\ln(q+1) + k_2]}{n^{0.43}} \tag{16}$$

where k_1 and k_2 were buffer constants and n is the number of amino acid residues in the peptide. This modification of the basic equation includes contributions to size by shape and length of the peptide chain. A plot of mobility versus hydrophobicity suggested a causal relationship with increased molecular mass. However, because the size parameter is based on number of residues and not molecular mass of the amino acids,

these authors could not directly account for an increase in peptide molecular mass. A further difficulty lies in the inability to estimate the effects of buffer ions and ionic strength on the double layer of the peptide chain; however, one would expect an increase in the value of the exponent for a compact molecule as ionic strength increased. Issaq et al.,[41] comparing Grossman et al.'s model with Offord's, concluded that $kq/M^{2/3}$ gave the best correlation for small polyalanine peptides in 50 mM ionic strength buffer. However, Chen et al.,[42] carrying out a study similar to that of Rickard et al.,[21] found the best correlation with $M^{-1/2}$; likewise, Survay et al.[43] obtained the best fit of their data to Grossman et al.'s model, rather than Offord's model. Castagnola et al.[44] found a good correlation with Grossman et al.'s model with $n^{0.5}$ for tryptic peptides from horse myoglobin.

Hilser et al.[45] found that Grossman et al.'s model gave a better fit with tryptic peptides derived from recombinant human insulin-like growth factor I than Offord's model. Further inspection indicated that both models inadequately treated peptide size, and a more complex treatment including thermodynamic functions of enthalpic and entropic contributions of polar and apolar moieties was required to improve the ability to predict peptide migration.

Compton[46,47] attempted to reconcile the differences in these two approaches by developing a model based on Debye–Hückel–Henry theory, demonstrating that ionic strength would influence the mobility–mass relationship depending on the magnitude of the polymer molecular mass and the ionic strength of the buffer. In fact, mobility is a continuous and complex function of molecular mass between the limits of $M^{-1/3}$ and $M^{-2/3}$. For compact polymers in low ionic strength solutions one would expect mobility to reflect a dependence on $M^{-1/3}$; for larger molecules in high ionic strength buffers, $M^{-2/3}$ would dominate. Hence the dependence observed by Grossman and others would be indicative of moderate polymers in a medium ionic strength buffer.

In a comparison of the models of Offord, Grossman et al., and Compton, Cifuentes and Poppe[48,49] found good agreement with any of the three models when constants were chosen appropriately. They attempted to account for the electrostatic interactions of the charges within the polymer, deriving Equation (17):

$$\mu = \frac{A[\log(1 + Bq)]}{M^C} \tag{17}$$

From a set of 48 peptides, these investigators obtained values of $A = 1758$, $B = 0.297$ and $C = 0.411$.

Application of Equation (15), (16) or (17) to the prediction of mobility of peptides is relatively straightforward. The charge on the peptide may be calculated by the Henderson–Hasselbach equation at the buffer pH, using the ionization constants of the component amino acids. While the p*K*s of the side groups are typically assumed to be identical to those of the individual free amino acids, the C- and N-terminal ionization constants may differ by one or two orders of magnitude. Within the peptide, the ionization constants of individual residues may be affected by neighboring side chains, the local dielectric constant due to solvation and the ionic strength of the medium. Tabulated values for amino acid functions are available from Skoog and Wichmann,[50] Rickard et al.,[21] Pennio[51] and van de Goor.[38] Several computer programs have also been developed to simplify the process by simply entering the sequence, if it is known (CHARGEPRO™ and PHYSCHEM™, IntelliGenetics, Mountain View, CA; Compudrug Chemistry, Budapest, Hungary). The predicted migration may then be adjusted (most typically by modifying the pH of the buffer) to obtain the desired separation of the analytes of interest.

With respect to buffer pH, a number of reports have evaluated the importance of the separation pH in predicting peptide mobility based on charge and size. Castognola et al.[52] interrogated the importance of the Stokes radius as a function of the peptide pH. Since the Stokes radius of the peptide changes with pH, one would predict that the accuracy of peptide migration would change as solution pH is altered – this is not accounted for by the standard equation. Applying ''best-fit'' procedures to CE mobility data, the authors found the best predicative pH region to be 2.25–2.5 where the polymer Stokes radius relates to mass by the coefficient 0.68, close to Offord's 2/3, and suggests that the Grossman et al.[53] approach using the p*K*s of free amino acids is insufficient. This same topic was further explored by Castognola et al.[12] using 2,2,2-trifluoroethanol (TFE) as an organic solvent in the separation buffer. This is a clever approach to interrogating predictive models since TFE modifies both the charge and Stokes radius. They found that predictions of mobility, size and charge were best in the pH range 2.0–2.5. This is likely due to the C-terminus being protonated, which the authors suggest eliminates an intramolecular ion pair causing a more compact form and exposing the apolar side chains; as a result the predication becomes less accurate.

3.2 Interrogating Peptide Structure

As indicated above, selectivity (resolution or separation) in CE is determined by differences in analyte electrophoretic mobility. Electrophoretic mobility is a function of analyte charge and size (more specifically, hydrodynamic volume). The charge on the molecule is most readily influenced by the pH of the separation medium; hence the buffer and pH are typically the first operating parameters optimized. Additives, such as

organic solvents which modify microenvironmental pH and solvation of the analyte, or salts, organic or inorganic, which alter the ionic double layer and the protein microenvironment, can also be used. Compounds that complex or interact with specific functional groups may alter the size or shape of the peptide and thus affect mobility.

3.2.1 Buffer Type and pH

The choice of separation medium (buffer) is critical to obtaining successful separations of analytes. Once the optimum wavelength for detection of the analyte(s) has been established, a buffer is required that does not interfere with the ability to detect the analytes of interest but maintains the solubility of the analytes, maintains buffering capacity through the analysis and permits the desired separation. It is important to prepare buffers with reagents of the highest quality, including Milli-Q (or equivalent) purified water, and filtering the buffers through a 0.22- or 0.45-μm filter to remove any particulate matter. Buffers stored at 4 °C should be brought to room temperature and degassed before use.

A variety of electrolytes can be used to prepare buffers for CZE separations. With absorbance detection, a major requirement of all components of the buffer is a low UV absorbance at the wavelength used for detection. This restriction substantially limits the choices to a moderate number of nonUV-absorbing electrolytes. However, a number of UV-absorbing organic buffers have been used with success at low concentrations to minimize background absorbance. At low pH, phosphate, acetate, formate and citrate have been used effectively; in the basic pH range, Tris, tricine, borate and 3-(cyclohexylamine)-1-propane sulfonic acid (CAPS) are acceptable electrolytes. For detection modes other than UV absorbance, a number of other electrolytes can be utilized. In fact, for indirect detection, a buffer with high background absorbance to allow lower detection limits of analytes is desired; thus chromate or phthalate are often utilized. For electrochemical detection, the buffer must be compatible with the analytes and also present a stable background conductivity against which the analytes can be detected.

When information about the sample is available, it is advisable to choose a buffer pH that approximates the pK of the solute mixture. This choice is relatively simple with pure or partially purified preparations; however, with crude biological mixtures, the pK_{avg} will typically be close to neutrality. Note that increasing the pH between 4 and 9 will result in an increase in the EOF. The buffer pH may be altered in a secondary manner by other parameters such as temperature, ion depletion of the buffer (caused by repetitive use of the same separation buffer) and organic additives. Examples of the effect of buffer pH on CE separation is given in Figure 4(a) and (b) for a series of peptides. The separation of a mixture of five peptide "isomers" representing residues 101–112 from the thyroid stimulating hormone (TSH) over a wide range of pH values is illustrated. At pH 2.5, all five peptides (differing only in sequence, not composition), which are identical in amino acid composition but vary in sequence, comigrate as a broad peak (not shown). At pH 8.61, the peptides migrate as two groups, while at pH 11.64 the resolution of four of the five peptides is observed.[54]

Figure 4 Dependence of peptide separation on buffer pH. Five peptides containing the same 12 amino acids but in varied sequence were analyzed at (a) pH 8.61 and (b) pH 11.64. Sequence of native peptide: (1) KTNYCTKPQKSY; (5) reverse sequence. Experimental conditions: 100 mM borate buffer with 10 mM diaminopentane, adjusted to the required pH with NaOH; 25 kV running voltage; 50 μm × 27 cm (20 cm to detector) capillary. (Reproduced by permission from Oda et al.[61])

3.2.2 Buffer Concentration and Ionic Strength Effects

Several parameters define the useful buffer concentration, including the capillary length and internal diameter, the applied electrical field strength and the efficiency of the capillary thermostating system. Generally, the use of moderately high ionic strength buffers is desirable for suppression of ion-exchange effects between the charged analyte ions and the ionized silanol groups on the capillary

wall. However, the current (Joule heat) associated with buffer concentrations greater than 100 mM may overcome the capillary thermostating capability of the system at higher applied voltages; excessive Joule heating may affect both resolution and analyte stability. Buffers that may be problematic include those containing high-mobility electrolytes such as chloride, citrate, phosphate and sulfate. The excessive Joule heating associated with high-concentration buffers can be circumvented in two ways. The easiest solution is to lengthen the capillary so that a tolerable current is maintained (decrease the field strength). However, this will increase the effective capillary length and may compromise resolution or detection if excessive diffusion or analyte–wall interactions occur. A reduction in cross-sectional area of the capillary will also reduce heating by decreasing the current flux density, allowing for more effective dissipation of heat due to a greater surface-to-volume ratio. Alternatively, buffers that run at relatively low current (and Joule heat) can be used. One such buffer in the pH 7–9 range is borate buffer, which has been shown to be an excellent CE buffer at concentrations as high as 500 mM.[55] This may be useful for the CE separation of fluorescently derivatized peptides in the neutral pH range. An added advantage of using a higher ionic strength separation buffer is the increased sample loading capacity that results from the on-capillary stacking effect, as described in an earlier section.

The method described by Nelson et al.,[19] termed the ''Ohm's law plot'', allows for facile determination of the 'functional' buffer concentration and the maximum voltage that can be utilized with the particular buffer system (i.e. the functional limit for capillary thermostating), and allowing for adequate equilibration, voltage is applied to a buffer-filled capillary (Figure 5) for short time intervals (e.g. 1 min) and the current recorded as the voltage is incrementally increased. When current is plotted as a function of voltage, loss of linearity indicates that the thermostating capacity of the system has been exceeded (i.e. the generated Joule heat is not effectively being dissipated). One should strive for heat generation of $<1\,W\,m^{-1}$ for optimum separation and it should not exceed a power of $5\,W\,m^{-1}$.[56]

Figure 5 Determination of optimum separation parameters using the Ohm's law plot. Current is plotted against applied voltage for each of three buffers as the applied field is incremented at $2.5\,kV\,min^{-1}$. Buffers were: 100 mM phosphate (pH 2.5), made by dilution of phosphoric acid and titration with NaOH; 100 mM borate (pH 8.3), made by titrating 25 mM sodium tetraborate with 100 mM boric acid; and 100 mM CAPS (pH 11.0), made by titration of the appropriate concentration dissolved in water with NaOH. The lines indicate the linear portions of the plots. The departure from linearity indicates the excessive increase in current at the applied voltage, and is a reflection of the increase in the capillary temperature.

Increasing the ionic strength of the separation buffer increases the thickness of the ionic double layer, and has the effect of decreasing the EOF, hence increasing the separation time. An advantage of increased ionic strength, in addition to the obvious improvement in buffer capacity, will be to decrease analyte–wall interactions.[57] The net effect on the separation, therefore, will be to increase the resolution, provided that the capillary thermostating capability is not exceeded and that unwanted analyte dissociative processes (e.g. ligand–peptide/protein dissociation) do not occur. On the other hand, an increase in ionic strength might improve resolution in mixtures by decreasing nonspecific analyte interactions. As mentioned above, increasing the ionic strength will also increase the current at a constant voltage, hence adequate thermostating of the capillary may become a concern. Also, use of buffers with poor transparency in the low-UV region (e.g. citrate, $\lambda_{max} = 230\,nm$) may have adverse affects on detection sensitivity.

3.2.3 Augmenting the Separation Buffer with Additives

The selectivity in peptide separations can be enhanced with the use of buffer additives. Several classes of additives have been identified as applicable to CE and, as seen in Table 1, the additives are multifunctional, not only suppressing analyte–wall interactions, but also affecting analyte solubility and in some cases selectivity.

3.2.3.1 Organic Salts A number of organic modifiers have been used successfully in peptide CE with the effect being dependent on the nature of the additive. Positive effects on separation result from alteration of the solvation properties of the modified buffer on the analyte or diminished EOF due to changes in the thickness of the double-ionic layer (and hence the zeta potential) or reduction of the viscosity of the buffer. For example, the addition of 1,4-diaminobutane to the buffer has been proposed to enhance resolution by slowing the

Table 1 Common buffer additives in CE and their effects

Additive	Example	Function
Inorganic salts	NaCl, $CaCl_2$, K_2SO_4	Modification of EOF; protein conformational changes; protein hydration
Organic solvents	Methanol, acetonitrile, ethylene glycol	Modification of EOF; analyte solubilization; analyte solvation
Organic additives	Urea	Modification of EOF; protein solubilization; denaturation of oligonucleotides
Sulfonic acids	Hexane, heptane, octane or nonane analogs	Analyte ion pairing; hydrophobic interaction
Divalent amines	Diaminoalkanes, hexamethonium bromide, decamethonium bromide	Modification of EOF; charge neutralization; analyte interaction
Cationic surfactants	Dodecyltrimethylammonium bromide, cetyltrimethylammonium bromide, tetradecyltrimethylammonium chloride	Charge reversal on capillary wall; hydrophobic interaction
Cellulose derivatives	Hydroxyethylcellulose, methylcellulose, hydroxypropylmethylcellulose	Reduce EOF; provide sieving medium

EOF through a dynamic modification of the capillary wall.[58–60] Ion-pairing agents, such as alkylsulfonic acid salts, have been used with success to resolve peptides.[61] Figure 6 demonstrates the influence of HSA on the separation of a series of peptides of identical amino acid composition but differing sequence. Here the resolution appears to be due to the differential solvation and/or the micro-environment of nearest neighbor effects on pK values of the charged amino acids.

3.2.3.2 Organic Solvents Organic solvents, such as methanol or acetonitrile, decrease both the conductivity of the buffer and EOF through their ability to disrupt the ordered structure of the water molecules. Enhancement of resolution may result from a combination of the decreased EOF (i.e. increased on-capillary time), decreased thermal diffusion and improved analyte solubility. In Figure 6(a–c) the effect of acetonitrile concentration on the solvation and resolution of the same series of peptides is shown.[61]

3.2.3.3 Chiral Agents In the pharmaceutical industry, it is important to have the ability to resolve closely related impurities and degradation products in drug formulations. Skanchy et al.[62] explored the separation of potential degradation products of a dipeptide using a novel anionic cyclodextrin, $SBE[4]_{ds}(1–10)_{sr}$-β-CD, as a pseudostationary phase for the CE separation. Evaluating a variety of neutral and anionic cyclodextrins as well as pH and the cyclodextrin concentration, they found that the stereoisomers of an Asp–Phe dipeptide (α-D,L, α-L,D, α-D,D) could be optimally resolved from the α-L,L parent compound using low concentrations of sulfobutyl ether-derivatized β-cyclodextrin at an acidic pH. This is significant in light of the fact that, to date, dipeptide stereoisomers have only been separated with chiral buffer additives or neutral cyclodextrins.

Figure 6 Enhanced peptide resolution afforded by the use of organic additives. The combined effect of acetonitrile and hexanesulfonic acid (HSA) on the separation of the peptides in 50 mM phosphoric acid (pH 2.0). Separation was carried out in a bare fused-silica capillary, 50 μm ID × 57 cm long (50 cm to the detector) at 15 kV and 28 °C with detection at 200 nm. (Reproduced by permission from Oda et al.[61])

3.2.4 Other Modes

3.2.4.1 Micellar Capillary Electrophoresis of Nonglycosylated Peptides MCE is a mode of CE which exploits

the micelle-forming properties of surfactants to partition neutral molecules according to their hydrophobic character. While this mode has typically been used for the analysis of small, drug-like molecules, it has also been used with some success for the resolution of peptides. Grimm et al.[63] improved upon a CZE method used for the separation of urinary imidodipeptides of prolidase-deficient patients exploiting MCE for disease screening. Using 65 mM SDS as the micellar phase in a pH 8.3 borate buffer, MCE separation allowed the collection and sequencing of almost all peaks for definition of the imidodipeptide composition of the urine. Once accomplished, imidodipeptide excretion patterns based on MCE separation may be used for disease diagnosis as well as determining severity. A follow-up paper from this group[64] evaluated different surfactants in an attempt to optimize the separation of the urinary imidodipeptides. After trying three nonionic and four anionic detergents and also varying detergent concentration, pH and temperature, with and without organic solvents, they determined that the urinary imidodipeptides were optimally resolved in a pH 9.3 borate buffer containing 50 mM pentanesulfonate and 10% methanol at 10 °C.

3.2.4.2 Capillary Isoelectric Focusing Several researchers have begun to explore CIEF as a powerful alternative to CZE because it allows for large sample volumes to be loaded on the capillary without adverse effects on resolution. While more typically associated with protein analysis, recent studies have begun to show its utility for peptide analysis. Shimura et al.[65] showed the effectiveness of peptide CIEF when coupled with laser-induced fluorescence (LIF) for sensitive detection. Using a nine-amino-acid peptide containing a cysteine, rhodamine labeling (at the thiol) was followed by trypsin digestion, which generated a six-amino-acid product. CIEF of the tryptic digest allowed the detection of the peptide product in the low picomolar range. Unfortunately, the authors did not demonstrate the application of CIEF with LIF to more complex samples. Taking a different approach, Wu et al.[66] exploited imaged CIEF for the analysis of peptides as a means of circumventing the drawbacks associated with EOF or pressure mobilization of the focused zones in conventional CIEF. Whole-column imaging can reveal these methodological problems and their ramifications, including increased analysis time, uneven resolution and uneven mobilization speed. In this study, they demonstrated the successful imaged focusing of a synthetic peptide, although the significance of this sequence was not defined by the authors. The presence of 20% glycerol appears to be required for effective focusing and while both fluorocarbon- and polyacrylamide-coated capillaries were used in this study, it is not clear which was used in this particular experiment.

3.2.5 Peptide Dimerization

Landers et al.[36] studied cysteine-mediated peptide homo- and heterodimer formation using CZE. Using a low-pH citrate buffer, they were able to monitor the kinetics of homodimer formation with a 28-amino-acid N-terminal cysteine peptide and a 13-amino-acid C-terminal cysteine peptide. Low-pH CZE allowed the deciphering of the time course for formation of the homo- and heterodimers when both peptides were incubated with H_2O_2 with a 12-min separation. LeTourneau and Allen[67] carried out similar studies using glycopeptides where homodimerization correlated directly with the antibacterial activity, e.g. vancomycin and ristocetin A. Using CZE in a neutral phosphate buffer, they were able to evaluate the dimerization of the three antibiotics (vancomycin, ristocetin A and LY264826) in the presence of a bacterial cell wall analog. Based on the mobilities, the glycopeptide antibiotic dimerization constants determined by CE were consistent in trend with those obtained by nuclear magnetic resonance (NMR) spectroscopy and sedimentation equilibrium, but generally smaller in magnitude.

3.2.6 Detection

3.2.6.1 Derivatization In order for CE to be effective for many of the applications involving peptide analysis in biological systems, sensitive detection schemes are needed. This often requires the employment of fluorescence detection and, in particular, LIF detection. Despite the intrinsic fluorescence of the aromatic amino acids (Tyr, Trp, Phe), fluorescent derivatization is often required for sensitive and unbiased detection. Common reagents for derivatization include fluorescein isothiocyanate (FITC), *o*-phthaldialdehyde (OPA), naphthalene-2,3-dicarboxyaldehyde (NDA), fluorescamine and 3-(4-carboxybenzoyl)quinoline-2-carboxaldehyde (CBQCA), while less common derivatization reagents such as fluorescein succinimidyl ester (FSE) have also been tested.

Zhu and Kok[68] studied the reaction kinetics for the postcolumn derivatization of peptides using fluorescamine and compared the labeling, both in effectiveness and detection sensitivity, with OPA. Using an uncoated capillary and a borate buffer at pH 9.5 for peptide separation, fluorescamine was found to be superior to OPA, providing limits of detection of ~0.1 μM. This was approximately 10 times better than the detection limits attainable with UV detection and, consequently, nanomolar to micromolar quantities of peptides are needed.

SP, a basic undecapeptide with a hydrophobic C-terminus, is a member of the tachykinin family, present in the central and peripheral nervous systems, and has a wide range of biological effects. The presence of this protein in brain fluid at picomolar concentrations has been

associated with schizophrenia and Huntington's, Parkinson's and Alzheimer's diseases. In order to elucidate the function of SP and the contribution to its modulatory effects made by its metabolites, Whelpton et al.[69] used CE in combination with HPLC to study the in vivo metabolism of SP in rat striatum. CE was used to separate the fractions from gradient elution HPLC and to avoid the high background signals when detecting at a low wavelength (214 nm) in HPLC. Based on the migration times, SP and significant amounts of its N-terminal fragments, SP (1–7) and SP (1–4), were detected but not the major C-terminal fragments at the concentration studied (10 nmol in the rat by intrastriatal injection). The CE results showed that the metabolism of SP has zero-order elimination kinetics with a rate of decay of 0.2 nmol min^{-1}. The N-terminal metabolites may contribute to the overall pharmacological pattern of activity of the parent peptide as SP (1–4) and SP (1–7) are produced in vivo in the striatum in relatively large amounts. Kostel et al.[70] also studied SP via direct sampling from brain tissue using microdialysis. Pseudo-real-time monitoring of tissue using this technique involves continuous sampling of brain fluid at approximately 1 μL min^{-1} and provides volumes compatible with CE. Using a postcolumn derivatization involving naphthalene-2,3-dicarboxaldehyde-β-mercaptoethanol (NDA-β-ME) and an etched reactor in the membrane, they examined the detection enhancement in response to varying pH and reaction time. They observed a limit of detection of ~75–100 nM for lysine-containing peptides, but only 20–25 μM for non-lysine-containing peptides with 12-s reaction times.

Chen et al.[71] studied the fluorescent labeling of [D-$Pen^{2,5}$]enkephalin (DPDPE), a synthetic opioid peptide used as a highly selective delta-receptor agonist in studies of receptor–ligand binding. Following solid-phase extraction (SPE) of serum samples on C_{18} and fluorescent derivatization with tetramethylrhodamine-5-isothiocyanate isomer G, a CZE/LIF method was used to quantitate the DPDPE in rat serum. The on-column detection limit for this method was 1.3 amol (10^{-18} mol) of DPDPE, much higher than in HPLC (the analysis range is 50–100 μM) and CZE/UV detection (the detection limit is 0.4 μM). Their results show that this CZE/LIF method could be used for the sensitive and specific quantitation of therapeutic peptides in biological matrices.

3.2.6.2 Solid-phase Extraction/Capillary Electrophoresis for On-line Concentration and Analysis of Peptides

An alternative to derivatizing peptides for low-level detection using LIF is to concentrate the solutes of interest from large volumes on-capillary. This can be accomplished using solid-phase extraction/capillary electrophoresis (SPE/CE), which involves nothing more than creating a nanoliquid chromatographic column at the inlet of the capillary. Using as little as 100 μg of C_8 or C_{18} resin packed into a microscale device as illustrated in Figure 7, a bed volume between 50 and 500 nL can be created. Guzman et al.[72,73] led the way in this area, along with contributions from Debets et al.[74] and Merion and co-workers.[75,76] These devices, when fastened to the capillary inlet, can be used to adsorb solutes from 1 to 1000 μL with good efficiency and have been demonstrated to be effective for a variety of analytes.[77] More importantly, SPE/CE has been shown to be extremely effective for peptide analysis at concentrations below the detection limit with standard CE by our group[78,79] and others.[80] Figure 8(a–c) shows the ability of the on-line SPE device for concentrating peptides. A mixture of standard peptides, when diluted below the limit of CE/UV detection (200 nm), can be detected when 20 μL of standard are concentrated on the SPE device and eluted in a ~50 nL volume. Figure 9(a) and (b) shows how this approach is effective for real peptide samples. Reversed-phase high-performance liquid chromatography (RPHPLC) fractions of 100 μL each are analyzed directly by CZE (once the acetonitrile has evaporated, leaving 55 μL). Interestingly, these fractions, containing peptides generated by an in-gel trypsinization of bovine serum albumin (BSA), including fraction 3, would all be expected to contain peptides based on absorbance with RPHPLC. However, two-dimensional analysis with CZE clearly shows peptides in all fractions except 3. This fraction was thought to contain a contaminant extracted from the acrylamide gel.

Figure 7 Diagrammatic representation of the construction of a SPE tip.

Figure 8 Comparison of standard CE and SPE/CE for the analysis of peptides. (a) Separation of a standard peptide mixture containing (1) bradykinin, (2) angiotensin, (3) α-melanin-stimulating hormone, (4) thyrotropin-releasing hormone, (5) luteinizing hormone-releasing hormone, (6) leucine enkephalin, (7) bombeoin, (8) methionine enkaphalin and (9) oxytocin, all at individual concentrations of 50 mg mL^{-1}. Separation was carried out in a 57-cm capillary containing 50 mM phosphate buffer (pH 2.50) at 20 kV with the capillary thermostated at 25 °C. Sample was pressure injected for 10 s at 0.5 psi. Detection was at 200 nm. (b) Separation of the same mixture of peptides diluted 1 : 99 with 5 mM phosphate buffer (pH 2.50). Separation conditions as in (a). Sample was electrokinetic for 32 s at 8 kV. (c) Separation of the diluted peptide standards with SPE/CE where 20 mL of sample was loaded onto the packing by pressure (20 psi) for 1 min. Separation conditions as in (a). The bar represents 0.020 AU. (Reproduced by permission from Strausbach et al.[78])

Figure 9 Analysis of entire HPLC fractions in a single pass by CZE. (b) RPHPLC analysis of tryptic peptides from BSA. The peptides released from the tryptic digestion (0.4 µg) of 2 mg of BSA in a polyacrylamide gel slice were separated by HPLC and collected for two-dimensional SPE/CE analysis. The expanded figure identifies the peaks associated with the fractions collected from 31.5 to 34.0 min. (a) SPE/CE analysis of 55-µL HPLC fractions (100 µL prior to removal of acetonitrile) which were loaded onto the SPE capillary at 20 µL min^{-1}. Conditions for the separation were identical to those in Figure 8. (Reproduced by permission from Strausbach et al.[78])

4 POSTTRANSLATIONALLY-MODIFIED PEPTIDES

4.1 Glycopeptides

The biological role of oligosaccharides present in proteins has been subject to investigation since their discovery in the 1950s. These covalent components, originally thought to be artifacts, are now recognized to be important to the proper biological activities of these macromolecules, which include protein stability and solubility, biological recognition and function, antigenicity, transport and clearance. It has become increasingly clear that the intermolecular reactions associated with the function of glycoproteins involve both the carbohydrate and polypeptide portions of the molecule.[81] One aspect of glycoproteins that makes characterization difficult is their tendency to be ''microheterogeneous''. Cells do not synthesize a single glycoprotein, but instead produce a family of glycosylation variants differing in their oligosaccharide content. It is thought that, while each member of this cellular pool of glycoforms may have

a unique biological activity, the molecular characteristics necessary for structural integrity are maintained. As a result, the combined functional activities of the glycoforms provide a continuum of biological activity which the cell can control with high fidelity by varying the relative amount of each glycoform.

From an analytical perspective, glycoproteins form a separate class of proteins whose structure is complicated by the presence of the surface carbohydrates. The oligosaccharides add a second dimension of complexity to the glycoprotein structure, as a result of the types of linkages possible between the oligosaccharide and the protein, as well as the variety of monosaccharides which compose the glycan. Oligosaccharides may be covalently bound to the protein via linkage to the amide nitrogen of the asparagine side chain (N-linked) or through the oxygen of serine, threonine and, occasionally, hydroxyproline (O-linked). In addition, oligosaccharides can be further classified based on the monosaccharides which constitute the glycan. The N-linked oligosaccharides are typically (1) ''high-mannose'', composed of only mannose and *N*-acetylglucosamine, (2) ''complex'', containing a combination of galactose, fucose, neuraminic acid, mannose and glucosamine, or (3) ''hybrid'', composed of the elements of both the high-mannose and complex oligosaccharides. O-Linked oligosaccharides generally have fewer branches than their N-linked counterparts, but have more diversity with respect to the monosaccharide units which constitute them. These include glucose, xylose, *N*-acetylgalactosamine and arabinose in addition to the monosaccharides found in the N-linked structures.

The chemical structure of oligosaccharides presents some unique analytical problems in comparison with other biologically active molecules, whether the intact glycoprotein (and its glycoforms) or the glycopeptides (formed from selective enzymatic digestion of the protein) are analyzed, or whether just the oligosaccharides are analyzed following cleavage from the protein. The molar absorptivities for carbohydrates are remarkably low in the UV range and, therefore, preclude them from detection by fluorescence and absorbance methods, the most universal detection modes. Furthermore, saccharides are generally similar in structure, being polar and uncharged, and thus are difficult to separate in an unaltered form by RPHPLC or supercritical fluid chromatography (SFC). Oligosaccharides can be effectively resolved with a number of standard methods once appropriately derivatized: HPLC[82–94] and gas chromatography[95–99] using absorbance,[100,101] refractive index,[91] fluorescence[102,103] and electrochemical[86–94] detection schemes have been effectively used. The high resolving power of CE was recognized as a means to resolve individual glycoforms, providing the glycobiologist or carbohydrate chemist with the ability to answer many of the structural and biological questions that surround glycoprotein science. These studies made use of the extensive structural work done over the past several decades by glycobiologists. However, the difficulty in resolving the glycoforms of well-characterized glycoproteins has highlighted the idiosyncratic nature of some separations.

Taverna et al.[58] analyzed the glycopeptides obtained by tryptic digestion of rt-PA and isolated two glycopeptide fractions by RPHPLC. CZE of glycoprotein fraction 2 (GP-2) in a bare silica capillary gave the same elution pattern whether the buffer was 150 mM borate (pH 9.1) or 100 mM phosphate (pH 6.6), suggesting that minimal borate complexation occurred due to terminal sialic acids. The glycopeptide fraction 3 (GP-3) was best resolved in a 50 mM tricine buffer (pH 8.5) containing 2.5 mM diaminobutane (DAB); the authors suggested that the improved resolution was due to the slowing of EOF by the divalent DAB.

Wu[104] used CZE as a second dimension for the two-dimensional analysis of complex peptides resulting from the tryptic digest of recombinant tissue plasminogen activator. The first dimension, RPHPLC, lacked the resolution required to resolve the microheterogeneous glycopeptides, a task perfectly suited to CZE. Although high-performance anion-exchange chromatography (HPAEC) is capable of such separations, it suffers limitations in that only N-linked carbohydrates are separated and relatively large amounts of sample are required.

4.2 Micellar Capillary Electrophoresis of Glycopeptides

As mentioned earlier, MCE can be exploited for the separation of neutral molecules according to their hydrophobic character. This mode has also seen use for the resolution of glycopeptides, owing to the chromatographic partitioning of the neutral glycans into the micelle.

In the analysis of interferon-γ glycopeptides by CE, James et al.[105] separated the glycoforms in a bare silica capillary using 400 mM borate–100 mM SDS (pH 8.5). The proteins separated into three groups: PG1, containing the diglycosylated forms (Asn 25 and Asn 97); PG2, containing the monogylcosylated protein (Asn 25); and PG3, the nonglycosylated protein. Borate buffers in the pH range 8.5–9 gave the best peak resolution and shape, although the glycoforms were not resolved without the addition of SDS. Further characterization of the protein by PNGase F digestion resulted in a loss of complexity in the PG1 region, with an increase in complexity of pattern in the PG2 area. Longer digestion led to loss of peaks in PG2 with increase in peaks at PG3, and a final collapse of PG3 into a single, broad band, suggesting denaturation or proteolytic degradation. Some lower molecular mass

components were detected by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS/PAGE), suggesting the presence of a contaminating protease in the PNGase F preparation. Neuraminidase altered the complexity within a PG group, reducing charge heterogeneity without changing the basic three groups, indicating maintenance of structural variants between the fractions.

Attempts to separate glycoforms of other glycoproteins again indicate the idiosyncratic nature of glycoprotein resolution. James and co-workers[104] were able to separate the glycoforms of ribonuclease (RNAse) B and horseradish peroxidase, but were unable to resolve those of fetuin or α_1-acid glycoprotein (AGP) in 400 mM borate–100 mM SDS (pH 8.5), suggesting that terminal sialic acid residues might prevent partitioning into the micelle, thereby precluding resolution with this additive.

Glycopeptides have been relatively easier to separate. Nashabeh and El Rassi[106] investigated the CE separation of the glycopeptides obtained from AGP released by tryptic digestion. A complex pattern of peaks was observed following electrophoresis in a polyethylene glycol (PEG)-coated capillary containing 100 mM phosphate (pH 5.0). Parts of the electropherogram were correlated with fractions obtained by chromatography of the digest on a concanavalin A–Sepharose column. The complex pattern was attributed to glycosyl heterogeneity without identification of structures.

The retardation of electrophoretic migration of peptides containing glycosyl groups is highlighted in an elegant study by Rush et al.,[107] who produced a tryptic map of the glycopeptides of recombinant human erythropoietin. They were able to resolve 30 peaks in 80 min using 40 mM phosphate (pH 2.5), containing 100 mM heptanesulfonic acid as an ion-pairing agent (Figure 10). The electrophoretic pattern divided the peptides into nonglycosylated peptides migrating within 35 min and a glycosylated fraction from 40 to 80 min. Sialydase treatment resulted in peaks within the glyco window migrating faster, but still beyond 40 min, indicating that the neutral glycan retards the mobility of the glycan-containing peptides. *N*-Glycanase treatment resulted in a shift of peptides into the aglycone window (<40 min), as would be expected. Combining high-performance CE and HPLC as two-dimensional techniques, the individual glycosylation sites, Asn 83, Asn 24 and Asn 38, and an O-linked site were mapped. The authors suggested a strategy for the identification of glycosylation sites by a combination of RPHPLC and CE and possible assignment of structural identity of glycoforms based on the alterations in migration resulting from glycosidase digestion. This is certainly feasible based on the development of instrumentation for rapid two-dimensional HPLC/CE analysis by Larmann et al.[108] Sampling directly from a one-dimensional RPHPLC separation at regular intervals with CE analysis completed on the low seconds timescale in the second dimension, analysis of fluorescently labeled peptides from a tryptic digestion of horse heart cytochrome *c* was possible. Clearly, this type of analysis would be extremely useful for glycoprotein characterization.

Figure 10 CE separation of peptides and glycopeptides from recombinant human erythropoietin. The group of peaks with the faster mobility represent nonglycosylated peptides, and those with retarded migration are glycosylated. Experimental conditions: 40 mM sodium phosphate buffer with 100 mM heptanesulfonic acid at pH 2.5; 16 kV running voltage, 110 μA; 50 μm × 75 cm (50 cm to the detector). (Reproduced by permission from Rush et al.[107])

Rudd et al.[109] isolated five peaks, corresponding to the individual manno-5- through manno-9-containing glycoforms, from RNAse B. Analysis of oligosaccharides obtained by hydrazinolysis gave a pattern of five peaks, corresponding to the manno-5-through manno-9-glycomers. Using isolated fractions of RNAse B, Rudd et al.[110] investigated the structure–function relation of the glycosylation. Enzymatic digestion by *A. satoi* α-mannosidase reduced manno-5 to -9 (RNAse B5–9) glycomers to manno-5 (RNAse B5). RNAse B manno-1 (RNAse B1) was obtained by digestion with jack bean α-mannosidase. Mannosidase from *Helix pomatia* was used to produce a manno-0 (RNAse B0) isoform containing just the core *N*-acetylglucosamine residues. All glycoforms were separated on 50 μm × 100 cm bare silica capillary in 20 mM phosphate–50 mM SDS–5 mM borate buffer (pH 7.2) using a discontinuous voltage ramp, and collected preparatively. The isolated protein fractions showed no gross alterations in structure as reflected by H/D exchange rates monitored by NMR spectroscopy. Pronase proteolysis suggested no gross structural changes, as all glycoforms were more resistant to proteolytic digestion with a $t_{1/2}$ of 450 min for the glycosylated RNAses compared with 300 min for RNAse A. Comparing RNAse activity on whole-cell RNA, the glycoforms were more active: RNAse A (1.0, relative activity) : RNAse B0 (1.6) = RNAse B1

(2.2) : RNAse B5 (3.6) = RNAse B5–9 (3.8). These studies support the hypothesis that there might be a range of functional activity in the cell provided by glycoforms of an enzyme. Rudd et al.[110] noted that the individual glycomers might have differential activity against purified fractions of RNA; this hypothesis was not tested.

5 CONCLUDING REMARKS

As the Proteome Project enters our scope as the latest challenge for researchers in a quest to understand cellular processes in normal and pathological states, the ability to perform rapid and information-rich analysis of peptides will become critical. CE is a key part of the analytical arsenal that will be used to interrogate the complex array of components constituting the proteome. While CE has been established as a bona fide technique for peptide analysis, it is clear that we have not yet fully exploited this technology for application in the vast arena defined as peptide and protein analysis. The potential clearly exists for CE to provide a rapid means for not only interrogating peptide primary structure, but also for characterizing the myriad of post-translation modifications (e.g. phosphorylation, ribosylation, myristolation, methylation and hydroxylation). These capabilities will surely be enhanced by the effective interfacing of CE with other techniques. For example, Severs and Smith[112] have already demonstrated the power of MS as a detection method for CE in peptide analysis, and Moore et al.[111] have demonstrated, convincingly, the power of CE as part of a two-dimensional analysis of peptide mixtures. As these and other technological advances mature, as method development and instrumentation improve and as approaches for sensitive detection both in hardware and chemistry improve, CE-based peptide analysis will evolve into a robust, turnkey operation applied to a diverse array of applications.

ABBREVIATIONS AND ACRONYMS

AGP	α_1-Acid Glycoprotein
BSA	Bovine Serum Albumin
CBQCA	3-(4-Carboxybenzoyl)quinoline-2-carboxaldehyde
CE	Capillary Electrophoresis
CGE	Capillary Gel Electrophoresis
CIEF	Capillary Isoelectric Focusing
CITP	Capillary Isotachophoresis
CZE	Capillary Zone Electrophoresis
DAB	Diaminobutane
DPDPE	[D-Pen^{2,5}]enkephalin
EOF	Electroosmotic Flow
FITC	Fluorescein Isothiocyanate
FSE	Fluorescein Succinimidyl Ester
HETP	Height Equivalent to a Theoretical Plate
HPAEC	High-performance Anion-exchange Chromatography
HPLC	High-performance Liquid Chromatography
HSA	Hexanesulfonic Acid
ITP	Isotachophoresis
LIF	Laser-induced Fluorescence
MCE	Micellar Capillary Electrophoresis
MS	Mass Spectrometry
NDA	Naphthalene-2,3-dicarboxyaldehyde
NDA-β-ME	Naphthalene-2,3-dicarboxaldehyde-β-mercaptoethanol
NMR	Nuclear Magnetic Resonance
OPA	*o*-Phthaldialdehyde
PEG	Polyethylene Glycol
RNAse	Ribonuclease
RPHPLC	Reversed-phase High-performance Liquid Chromatography
SDS	Sodium Dodecyl Sulfate
SDS/PAGE	Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis
SFC	Supercritical Fluid Chromatography
SP	Substance P
SPE	Solid-phase Extraction
SPE/CE	Solid-phase Extraction/Capillary Electrophoresis
TFE	2,2,2-Trifluoroethanol
TSH	Thyroid Stimulating Hormone
UV	Ultraviolet
UV/VIS	Ultraviolet/Visible

As a result of their complex nature, the separation of proteins and glycoproteins by capillary electrophoresis (CE) is a challenge. Fortunately, a number of approaches allow for effective analysis of these biomolecules. Of particular concern is the proclivity of proteins and their glycoconjugates to adsorb to the capillary wall. Various covalent and dynamic capillary coatings are described which minimize this effect. We also address general concerns including electrode polarity, capillary conditioning and method development that are important for achieving optimal separation. Finally, each separation mode, including capillary zone electrophoresis (CZE), capillary gel electrophoresis (CGE), and capillary isoelectric focusing (CIEF), is discussed with particular attention to its niche in the realm of protein and glycoprotein analysis.

1 INTRODUCTION

Electrophoresis is a process that involves the movement of charged particles in an applied electric field. This concept, first defined by the moving boundary electrophoresis experiments of Tiselius[1] in 1937, was eventually adapted to slab gels in the early 1960s.[2,3] In this format, electrophoretic separation is performed through a cross-linked, porous gel polymerized between two plates. Slab gel electrophoresis, as well as adaptations in the tube format, provided the basis for a variety of electrophoretic modes to evolve and has been and remains a dominant force in the field of separations. In the early 1980s, Jorgenson and Lukacs[4] revitalized a technique that Hjérten[5] had pioneered more than a decade earlier and, thus, introduced CE to the scientific community.

1.1 Electrophoresis in a Capillary

CE involves the separation of analytes in narrow-bore capillary tubes which are typically composed of fused silica. The attractive aspects of CE stem from the fact that the instrumental control common to chromatography is now possible with electrophoresis. CE circumvents the labor-intensive and time-consuming processes associated with conventional electrophoresis (casting, loading, running, staining, and destaining) with little or no sample preparation, decreased analysis time, and on-column detection. Capillaries are typically less than 100 μm inner diameter by 375 μm outer diameter by 20–100 cm in length and provide a high surface-to-volume ratio permitting rapid dissipation of Joule heat.[4] As a result of the microscale dimensions, applied electric fields as much as 50 times that associated with slab gels can be routinely employed, enabling separations on the order of minutes or even seconds.[6]

A direct consequence of the microscalar nature of the capillary dimensions is the minute quantities of buffer and sample required for analysis. The total volume of the capillary, routinely 0.4–5.0 μL, translates to only microliters of reagent consumed per run. More importantly, the sample volume injected is restricted to approximately 1% of the total capillary volume (as low as 0.2 nL) requiring as little as 2–5 μL of sample for repetitive separations. The use of small volumes allows for the capillary to be easily rinsed and regenerated between

analyses with moderate pressure (10–50 psi), vacuum, or even gravity. The dramatic decrease in the amount of reagents used in CE, compared with slab gel methods, is directly linked to another advantage with the capillary-based electrophoretic approach – cost. Although the capital investment for commercial CE instrumentation or a homemade system is initially more expensive than slab gel equipment, the reduced cost for reagents, and small sample volumes, combined with dispensing of staining procedural costs, and the added benefit of automation, make CE an economical alternative.[7]

In addition to providing an instrumental approach to electrophoretic protein separations, CE allows for an on-line detection system, eliminating the need for staining and destaining procedures characteristic of the slab gel format. An electrophoresis technology that allows for evolution of detection from the semiquantitative staining procedure to direct wavelength-specific on-line detection has obvious merit. The problems associated with gel-based staining methods for detection of proteins are well-established and dependent heavily on a variety of parameters (stain source, stain age, temperature, specific protein, etc.), all of which affect staining efficiency and, thus, quantitation. Staining procedures are particularly problematic with glycoproteins as a result of stain binding interference by surface carbohydrate.

Although both optical and electrochemical detection methods have been demonstrated with CE, the optical techniques have been implemented more universally than the others. Ultraviolet/visible (UV/VIS) detection is the simplest to employ and applicable to a wide range of compounds including many biopolymers. However, the short pathlength of the optical cell (which is the internal diameter capillary itself) leads to poor concentration sensitivity and detection limits in the 10^{-6}–10^{-8} M range. It is in this respect that fluorescence detection is important, providing a more selective detection scheme and, in comparison with UV/VIS detection, sensitivity that is 100–1000-fold greater. Unfortunately, only the amino acids tryptophan, tyrosine, and phenylalanine fluoresce naturally and, therefore, most proteins must be tagged prior to analysis for laser-induced fluorescence (LIF) detection using simple (e.g. argon ion lasers) systems.

Yet another problem encountered with gel-based separations is poor reproducibility, particularly with two-dimensional systems. The quantitative reproducibility of CE is very good with typical migration time relative standard deviation (%RSD) values between 0.1% and 1.0%. In addition, for well-characterized CE systems, protein separation efficiencies reach 10^4–10^5 theoretical plates.[8] Thus, a technique surpassing the performance of its gel counterpart emerges, providing rapid, high efficiency, and reproducible separations with the added value of on-line detection and automation.

1.2 Instrumentation

A diagram of the instrumental set-up for CE is presented in Figure 1. The necessary components for this system include a capillary (outer surface polyimide-coated), a high voltage supply, two buffer reservoirs capable of accommodating the capillary and platinum electrodes, and an on-line detector. To perform a separation, the preconditioned capillary is filled with buffer and then sample is introduced at the inlet by pressure, vacuum, gravity or an applied potential. Using an uncoated (internal) fused silica capillary, under normal polarity, the inlet will be positive (anode) and the outlet negative (cathode). Both ends of the capillary are transferred to their respective buffer reservoirs where a separation voltage (up to 30 000 V) is applied. The charged species present in the sample plug migrate with an electrophoretic mobility deemed by their charge and mass (under nondenaturing conditions), and pass through the on-line detector, where information is collected and stored electronically.

Conventional separation techniques (such as gas chromatography (GC) and high-performance liquid chromatography (HPLC)) employ pressure gradients to pump the mobile phase and solutes from the column inlet to the detector. CE is unique in this respect in that it does not utilize a mechanical pumping mechanism for bulk flow. Instead, the physical configuration and chemical make-up of the capillary allow for an electric field-driven pumping of bulk solution during the electrophoretic process. Using an uncoated fused silica capillary and a normal polarity configuration (inlet → anode, outlet → cathode), ionized silanol groups on the capillary wall induce the formation of a double layer of cations (and their hydration spheres) which produce an electroosmotic flow (EOF) in the presence of an applied field (Figure 2a). The magnitude of this flow becomes significant ($\simeq 10^{-4}$ cm^2 V^{-1} s^{-1}) above pH 5–6 where the silanol groups will be largely deprotonated. EOF is responsible for the flow of analytes, regardless

Figure 1 Diagram of a CE instrument. An enlarged section of the capillary is shown to highlight the dimensions.

Figure 2 EOF and effects of wall coatings. (a) In most pH ranges (pH 3–11) a bare fused silica capillary has a negative surface charge. Consequently, cations in solution align, forming a positively charged double layer. Under an applied field and normal polarity (inlet → anode, outlet → cathode), the positive ions will move toward the cathode resulting in bulk flow toward the detector. (b) Coating with a nonionic layer shields the surface charge contributed by the silanols and thereby reduces the EOF. As the pumping mechanism has been minimized, the electrode polarity must be chosen so that molecules of interest migrate toward the detector. (c) Capillary coatings changing the effective charge of the wall from negative to positive will result in the formation of an anionic double layer. Consequently, the EOF is reversed and will be in the direction of the inlet (anode). Thus, only species with an electrophoretic mobility greater than the EOF will reach the detector under normal polarity. Reverse polarity may be employed for the detection of analytes with low electrophoretic mobility.

Figure 3 Diagram correlating EOF with pH. (a) At high pH, the capillary is largely deprotonated and therefore highly negatively charged. Consequently, a large EOF is present resulting in bulk movement of the solution toward the cathode. (b) The silanol surface of the capillary wall has a pK_a between pH 5 and pH 7. Around pH 5 a few silanol groups will be deprotonated and therefore a small EOF will exist in the capillary. As the pH is raised to basic, a larger fraction of the silanols will become deprotonated and therefore the EOF will increase within this range. (c) At low pH, the capillary wall will be mostly nonionic due to the protonated silanols. Here, the EOF is significantly diminished. Thus, the charge of the analyte and polarity of the electrodes determine which analytes migrate toward the detector.

of charge or size, to the detector. Thus, even neutral and negatively charged species will pass the detector as a result of the EOF, in most cases, being greater than the electrophoretic mobility of the anodically mobile species. EOF is largely (but not solely) governed by the buffer pH; a low-pH buffer produces relatively low EOF as a result of the decreased number of deprotonated silanols. Figure 3 illustrates the pH dependence of EOF. It is important to note that EOF results in the bulk movement of all analytes past the detector, therefore, a decrease in EOF will result in a situation where only solutes of like charge can be separated.[9]

1.3 Modes of Capillary Electrophoresis

Similar to the diversity found with standard gel electrophoretic techniques, several modes of CE have been established. These include CZE, micellar electrokinetic chromatography (MEKC), CIEF, and CGE. Although capillary isotachophoresis (CITP) has already been developed as a stand-alone mode for the analysis of proteins, it is primarily used as a preconcentration technique in CE. A basic knowledge of the existing similarities and defining differences between the modes is often necessary for optimizing a given separation. For instance, this may involve nothing more than use of a buffer additive to switch from one mode to another. Of the four main modes (CZE, MEKC, CGE, CIEF) only CZE, CGE, and CIEF play a major role in the CE analysis of proteins. These are described in the sections where they are discussed.

2 CAPILLARY ELECTROPHORESIS ANALYSIS OF PROTEINS AND GLYCOPROTEINS

Proteins and glycoproteins present a unique challenge to the separation scientist as a result of their complex nature. Crude or partially purified protein preparations are not trivial to analyze by CE due to the diverse nature of molecular masses and pH- and temperature-dependent stabilities that may be represented in the mixture. With

traditional denaturing slab gel electrophoresis, these inherent variations do not present a problem but, within the realm of CE where nondenaturing analysis is easily executed, these become important parameters.

Additional considerations associated with CE stem from the fact that separation is carried out in a capillary composed of fused silica, a substance with poor biocompatibility, especially for proteins. Under nondenaturing conditions, proteins have a propensity for adsorption to the capillary wall. This interaction must be minimized or negated if CE separation of proteins based on both charge and size is to be successful. A number of approaches are addressed in this review to deal with problematic areas of protein analysis. Once solved, CE evolves into an extremely powerful technique for biomolecule analysis.

Finally, glycoproteins are a group of macromolecules with complexity beyond that of nonglycosylated proteins as a result of the carbohydrate structures present on the protein surface. The carbohydrate moieties on the protein have been shown to be associated with numerous biological functions, including solubility, antigenicity, protein folding, transport, and clearance from the cell.[10] Additionally, abnormalities in glycosylation have been found to lead to or be the result of a number of pathological states.[11,12] To further complicate the issue, even purified preparations of certain glycoproteins are not trivial to analyze electrophoretically as a result of the inherent microheterogeneity that results from the natural variation in the carbohydrate content of the protein in biological systems. These glycoforms arise from the cellular production of a set of proteins that are identical in their polypeptide structure, but differ in their glycosylation with each serving a specific function within the cell. This microheterogeneity is thought to play a critical role in the high fidelity control of cellular processes.[10] It is clear that in order to understand the role of glycoprotein microheterogeneity in regulating complex cellular processes, their separation is a necessary component of biochemical research. This is often difficult if not impossible to accomplish with conventional electrophoretic formats. However, as will become clear in the sections that follow, nondenaturing separations by CE provide a new tool for interrogating glycoprotein structure and microheterogeneity.

3 FACTORS AFFECTING SEPARATION

3.1 Capillary Wall Interactions

One of the major problems that had to be addressed with early attempts to resolve proteins under nondenaturing conditions in fused silica capillaries was their nonspecific adsorption to the capillary wall. In the earliest studies by Jorgenson and Lukacs[4] the equation governing separation efficiency (derived by Giddings for chromatography)[13] was simplified based on the fact that, as this was electrophoresis and not chromatography, the partition coefficient k' in the radial diffusion term was essentially zero, giving Equation (1), where D is the diffusional coefficient

$$N = \frac{\mu V}{2D_{n,T}} \tag{1}$$

This made CE, in a sense, ''antichromatography''; with the assumption that $k' = 0$, band broadening (number of theoretical plates) would be primarily dependent on axial diffusion contributions. Due to the large molecular mass of proteins, diffusion would be relatively small and, therefore, calculated efficiencies of the order of 10^6 theoretical plates would be expected. However, this was not observed, even under the most ideal separation conditions. The inability to achieve predicted efficiencies was attributed to adsorption of analytes onto the highly negatively charged silanol surface of the capillary wall,[14] indicating that $k' \neq 0$ and, therefore, cannot be ignored. Swedberg's group at Hewlett-Packard has provided insight into this and shown that even small k' values (as low as 0.001) result in a substantial decrease in the achieved theoretical plate number.[15] Accordingly, attention must be paid to define CE conditions that strive to meet the assumption that $k' = 0$ (i.e. no wall interactions) for both peptides and proteins.

This can be accomplished for CE-based peptide separations with relative ease by working at pH extremes. At a basic pH of 10–11, both the capillary silanol groups and the peptides are fully deprotonated and, hence, negatively charged allowing for repulsion to prevent adsorption. At acidic pH of 1.9–2.5, the capillary silanol groups are fully protonated and, therefore, neutral in charge, while the peptides are cationic with no predominant proclivity for adsorption to the wall. Consequently, acidic peptides, difficult to resolve by reversed-phase HPLC methods, are readily analyzed in simple, low-pH buffer systems, such as 100 mM sodium phosphate, pH 2.5. This approach is extremely effective for peptide separations due, in part, to the fact that the peptides can easily withstand the extreme nature of the separation conditions. This is not the case with proteins where their stability is questionable outside the physiological pH range (pH 7.5). Although there have been some examples demonstrating that working at extremes of pH can be effective for protein analysis,[16] this is more the exception than the rule and precludes analysis in the most relevant pH range (physiological).[17] Furthermore, adsorption is still frequently observed even at high pH values (e.g. pH 10.0) above the isoelectric

point (pI) of many proteins. One must be cognizant that the pI is a net charge for the molecule and does not account for localized surface basic amino acids which may retain a positive charge even at extreme pH ranges. This phenomenon is exacerbated with proteins due to their increased surface area.

Thus, a challenge inherent in performing protein separations in silica capillaries, which is not encountered in HPLC or conventional electrophoresis, involves determining conditions that will minimize or even eliminate protein–wall interaction (i.e. $k' = 0$). Approaches for doing so have been evaluated extensively and involve either covalent or dynamic modification of the capillary wall or augmentation of the separation buffer composition. These are addressed in the sections that follow.

3.2 Buffer

Buffers play a major role in achieving a successful separation in CE. Ideally, CE buffers must maintain the solubility of the analyte, have good buffering capacity in the pH range of interest, and have low absorbance at the detection wavelength desired (typically 200 or 214 nm for proteins). There are a number of considerations for selecting an appropriate separation buffer. Most important is choosing an electrolyte. A number of effective electrolytes have been identified for protein separations at slightly acidic and basic pH ranges with borate and phosphate often employed. Another consideration is the ionic strength of the buffer. Higher buffer concentrations are obviously beneficial for increasing the buffering capacity of the solution, but they also influence the EOF by directly affecting the thickness of the ionic double layer (increased ionic strength → decreased EOF), and are associated with more current at high applied fields. As detailed in the article in this encyclopedia on **Capillary Electrophoresis of Peptides**, an Ohm's law plot (OLP) can aid in defining the functional concentration for a particular separation buffer.[18]

3.3 Capillary Coatings

In 1986, Lauer and McManigill[19] published a seminal paper demonstrating that protein separations could be achieved successfully in a bare silica capillary if wall adsorption was addressed. Over the past decade, research into the development of novel technologies for masking or eliminating the negative charge of the capillary wall has been productive. A number of unique covalent coatings have emerged to manipulate the EOF and minimize protein adsorption. Of equal importance, noncovalent (dynamic) approaches have been developed which also show promise in effecting protein separations in capillaries that exhibit degradation of efficiency due to adsorption.

3.3.1 Covalent Coatings

Capillaries can be functionalized (covalently coated) so that the inner walls are permanently modified. For example, a static wall coating usually consists of two chemical layers – the first reacts covalently with the silica, the outer layer being a hydrophilic neutral polymer. The polymer serves to shield residual silanol groups and increase the viscosity of the electric double layer, thus resulting in a substantial decrease, if not elimination, of EOF (Figure 2b). These coatings should be inert and resistant to degradation over a reasonably large pH range. The first material to be used as a covalent coating was polyacrylamide, a logical candidate stemming from its use in traditional slab gel electrophoresis techniques. Hjérten[20] was able to achieve near-zero EOF with polyacrylamide as the capillary coating for initial application to isoelectric focusing (IEF). Although effective, this coating suffered from stability and longevity problems.[21] Fortunately, improvements in coating procedures have minimized the problems associated with polyacrylamide coatings and commercial capillaries are now available.[9] Other, more traditional, polymer coatings including poly(vinyl pyrrolidone)[16] and poly(ethylene glycol)[22] have been employed for protein separation. In addition, a number of commercial capillaries have proved to be successful for CE-based protein separation including capillaries from the DB-series, where the coating is some dimethylpolysiloxane (originally developed for GC; J & W Scientific), fluorocarbon-coated capillaries (J & W Scientific), capillaries with an uncharged hydrophilic coating (Beckman eCAP Neutral™), anionic coated capillaries (CE-100-SA; Scientific Resources), and capillaries with a cationic coating (Celect-Amine™; Supelco).[9] Also, as a consequence of the necessity for stable, relatively inert coatings, a number of homemade capillaries have also been found to be effective for unique protein and glycoprotein separation systems.[23–28]

3.3.2 Dynamically Coated Capillaries

As an alternative to covalent passivation of the capillary surface as described in the previous section, dynamic coating of the capillary can also be carried out. This involves specific adsorption of solutes to the capillary wall, resulting in a temporary, yet stable, masking of the surface silanol groups. Depending on the nature of the dynamic coat, the negative charge imparted by the silanols is significantly reduced, eliminated, or in some cases reversed. The advantage of this approach lies in the simplicity, as it often involves nothing more

than augmenting the separation buffer with the dynamic coating additive at the appropriate concentration. As the dynamic coating is pumpable, it can be easily removed and regenerated.

3.3.2.1 Cationic Additives One approach to dynamically coating the capillary employs cationic additives some of which actually reverse EOF by changing the charge of the capillary wall from negative to positive (Figure 2c). In particular, long-chain alkyl quaternary amines (e.g. polybrene and cetyltrimethylammonium bromide (CTAB)), have been employed effectively for this purpose.[29–33] The cationic head of the amine aligns with the anionic silanols on the capillary wall so that the hydrophobic tail extends into the capillary core. Unbound surfactant molecules align with their hydrophobic tails binding hydrophobically, resulting in a pseudodouble layer and a cationic wall, thus resulting in a reversal of EOF. Employing a cationic additive, separation is carried out in a pH below the pI of the protein so the positively charged proteins will be repelled by the capillary wall. This differs from dicationic long-chain alkyl quaternary amines (e.g. hexamethonium or decamethonium bromide) where the surface is adequately passivated without the reversal of EOF.[34] Numerous reports in the literature demonstrate the success of diaminoalkane cationic additives for investigating proteins and their glycoconjugates.[19,35,36]

3.3.2.2 High-salt Buffers Increasing the ionic strength of the separation buffer can also be utilized to reduce protein–wall interactions. Lauer and McManigill[19] first illustrated this approach by adding potassium sulfate to their separation buffer. This prevented adsorption of standard proteins, with pI values ranging from 4.5 to 11, to the bare silica wall. Similar experiments conducted by Green and Jorgenson[37] employed alkali metal salts to reduce protein adsorption. Although effective, this alternative is associated with two main disadvantages: high molar absorptivity in the low-UV (ultraviolet) region and high current resulting in increased Joule heating.[17] The latter of these problems may be circumvented with the use of zwitterionic additives which can be added at molar concentrations without invoking high current with the use of high electric fields (their electroneutrality does not increase the conductivity of the buffer and creates a boundary layer of ions between the silanol layer and the proteins).[38,39] The effectiveness of this approach has been illustrated by Bushey and Jorgenson[40] for the resolution of basic proteins, and has since led to the use of many zwitterionic additives, including betaine,[41] CAPS (3-cyclohexylamino-1-propanesulfonic acid),[19] CHES [2-(N-cyclohexylamino)ethanesulfonic acid],[19] and tricine[19] for the successful separation of proteins. More detail on approaches for minimizing protein–wall interactions in CE is given in a number of excellent reviews on the subject.[9,17,42,43]

3.4 Protein Structure

An important factor involved in optimizing protein separation by CE is the protein itself. Many proteins are unstable in simple buffer solutions (precipitation, aggregation, etc.) and, consequently, solubilizing (detergents) or stabilizing agents (glycerol) must be present to maintain integrity. Where these might have a negligible effect with conventional slab gel electrophoresis, they can have significant impact on the CE separation. It is reasonable to assume that, once solubilized, proteins have an electrophoretic mobility solely dependent on charge and size. However, it is now apparent that a number of factors including, but not limited to, mass and charge contribute to a protein's mobility. For example, the electrophoretic mobility of an analyte is affected by the surrounding environment – in particular the buffer, any additives (organic modifiers), other analytes, and the capillary wall. In addition, one must be cognizant of the fact that the net charge of the protein is the total charge contribution from amino acids, metal ions, and cofactors. However, this charge is shielded by a number of environmental factors, including attraction to counter-ions in solution. Thus, it is the effective charge of a protein which contributes to mobility in an applied field.[44] The hydrodynamic radius of a protein is another important factor affecting mobility in an applied field. Kálmán et al.[45] demonstrated that mutants of nuclease A with a larger hydrodynamic radius had longer migration times than those proteins with smaller radii. Thus, for protein separations it may be more accurate to describe the mechanism of electrophoresis as a function of effective net charge and hydrodynamic radius instead of simply charge and size.

4 PRACTICAL ASPECTS OF CAPILLARY ELECTROPHORESIS

4.1 Theory

The equations governing mobility, shape of the analyte zone, resolution, efficiency, and sources of variance in electrophoresis are discussed in detail in **Capillary Electrophoresis of Peptides** and are therefore not addressed here. An in-depth treatment of these topics is also given by Giddings.[46]

4.2 Separation Parameters

With the numerous parameters that must be addressed when developing a method or optimizing a CE separation, it is imperative to have an understanding of the

interdependence of one parameter with another. For example, a protein separation can be profoundly affected by slight changes in the capillary dimensions. Specifically, if closely migrating species (e.g. protein glycoforms) are not adequately resolved, increasing the capillary length will increase resolution by affording a longer on-capillary time. However, a longer capillary is associated with increased analysis times which may become unfavorable with rapid separation schemes. Fortunately, increasing the capillary length decreases the electric field strength at constant voltage, thus allowing the application of higher electric fields (usually characterized by decreased migration time). Increasing the capillary diameter has advantages and disadvantages. An increase in capillary inner diameter will improve detection sensitivity by increasing the pathlength. However, a decreased surface-to-volume ratio accompanies an increased diameter, ultimately resulting in less efficient heat dissipation which is characterized by band broadening. It is important to note that these and other parameters (such as pH, EOF, field strength, etc.) can be effectively optimized to achieve separation conditions. An evaluation of the relationship of CE variables is given in a review by Oda and Landers.[47] Discussion is restricted in this text to only fundamental separation parameters.

4.3 Electrode Polarity

Determining the electrode polarity is of paramount importance to achieving a desired separation. Manipulation of the EOF via electrode polarity or capillary wall charge modification (through the use of coatings) enables selection of the analytes migrating toward the detector. As discussed earlier, normal polarity in a bare silica capillary is associated with an anodic inlet and a cathodic outlet. Here, positively charged species will move with the EOF and a characteristic mobility (based on charge and size) in the direction of the detector. Neutral analytes having no electrophoretic mobility will be carried with the EOF. In this system, negatively charged species will have an intrinsic mobility toward the inlet, therefore, away from the detector. However, the EOF is usually the dominating force (greater than electrophoretic mobility), thus allowing for separation and detection of anodically mobile analytes. In comparison, if the reverse polarity is set, the EOF will be in the opposite direction, away from the detector. In this case, positively charged analytes have a characteristic mobility toward the inlet (cathode) while neutral species are carried with the EOF in this same direction. Consequently, only negatively charged analytes with a mobility greater than the EOF will reach the detector. Reverse polarity is often employed when a coated capillary is used to separate negatively charged analytes or with substances that reverse the net charge of the capillary wall.

4.4 Injection

Regardless of the mode of CE utilized for separation, there are three primary methods for sample injection into the capillary: hydrodynamic, hydrostatic (by siphoning), or electrokinetic. Hydrodynamic injection is accomplished by immersing the capillary inlet into the sample and either pressurizing the sample vial or applying a vacuum to the outlet. Hydrostatic sample injection (by gravity), more common in noncommercial instruments, relies on siphoning of the sample into the capillary by elevating the sample vial relative to the outlet vial. Electrokinetic injection is accomplished by immersing the capillary inlet into the sample and, with the outlet in buffer, applying a low voltage to the system. This injection method is discriminating in that movement of the sample into the capillary depends on electrophoretic mobility and EOF. Consequently, components of the sample matrix with high electrophoretic mobility will be more likely than those with a lower mobility to be introduced into the capillary. The advantages of biased injection are discussed in detail in **Capillary Electrophoresis of Peptides**.

4.5 Capillary

The condition of the capillary has a substantial impact on the efficiency and reproducibility of a CE separation. This is particularly true when dealing with coated capillaries. Both the fused silica and coated capillaries can be purchased from a number of companies; however, treatment of the capillary prior to, during, and after an electrophoretic separation is crucial.

4.5.1 Conditioning

When using a new capillary or changing to a new buffer system the capillary must be conditioned. A typical conditioning procedure for a bare silica capillary is a 5–10 column volume rinse with 100 mM NaOH, followed by a 5–10 column volume rinse with water and, finally, a 3–5 column volume rinse with separation buffer. If the capillary is coated, conditioning should be performed as per the manufacturer's protocol.

4.5.2 Regeneration

Maintenance of the capillary surface is necessary for achieving reproducible results which are largely dependent on consistent EOF. However, during the course of a separation and, particularly after multiple separations, the surface may become fouled by the sample. For this reason, the capillary surface must be cleansed of any adsorbed species (i.e. regenerated) after each separation. For a bare silica capillary and neutral or basic buffer system, regeneration is typically achieved by rinsing 3–5 column volumes with 100 mM NaOH followed

Figure 4 A step-wise approach to method development for the analysis of proteins by CE; *l*eff is the effective length, T = temperature and EK = electrokinetic.

by a 5–8 column volume rinse with water and then separation buffer. When using an acidic buffer, NaOH regeneration may be disadvantageous as the drastic pH change may require extensive rinsing to reequilibrate the capillary. In this situation, following the water wash with a brief rinse with concentrated buffer (10× or more) and then separation buffer is the advised approach. Depending on the sample, the concentrated buffer wash may be effective for regenerating the surface. In this situation, the NaOH rinse can be completely eliminated. After extensive use, NaOH regeneration may not be effective for completely removing adhered species. Here, rinsing with sodium ethoxide (blended from equal volumes of 1 M NaOH and 95% ethanol) for 5 min is usually sufficient. The sodium ethoxide must be followed with 10–20 column volumes of water and then finally 5–8 column volumes of separation buffer. Regenerating a coated capillary is more complicated. When possible, it is best to follow the manufacturer's instructions for regeneration.

4.6 Method Development

The development of CE methods is as idiosyncratic in nature as with HPLC. Even slight heterology in the primary structure or differences in the secondary or tertiary structure of proteins (single amino acid substitution) can require dramatic changes in methodology. Consequently, separation conditions must be unique to the system of interest. Figure 4 illustrates a step-wise approach to designing a method for protein separation by CE.

5 SEPARATION METHODS

5.1 Capillary Zone Electrophoresis

CZE is the simplest form of CE and is the mode described in most of the previous discussion. With this technique, the capillary is filled with buffer, the sample injected, the separation voltage applied to the capillary reservoirs, and the charged species within the field move toward

Figure 5 CE separation modes. (a) CZE separates analytes based on charge and size. Once injected, the sample components migrate into zones determined by their electrophoretic mobility. Under normal polarity (inlet → anode, outlet → cathode) positively charged proteins will have a mobility greater than the EOF and reach the detector first. Neutral proteins having zero electrophoretic mobility will migrate with the EOF. Negatively charged proteins will have mobility in a direction opposite to the EOF. Fortunately, the EOF is often the dominating force and negatively charged species reach the detector. (b) In CGE mode, a static polymer coating is used to shield the silanols of the capillary wall, thus eliminating the EOF. The capillary is then filled with a chemical (cross-linked) gel or a physical (entangled) gel. Under denaturing conditions, the proteins are negatively charged. As a result, separation must be carried out under reverse polarity (inlet → cathode, outlet → anode) for the proteins to reach the detector. Under nondenaturing conditions, the protein's charge will be influenced by the pH of the buffer system. Consequently, electrode polarity may be normal or reverse depending on the conditions of the separation. (c) In CIEF ampholytes are introduced into the capillary to set up a pH gradient. Under an applied field charged species migrate (solely based on charge and size because a coated capillary is used to minimize the EOF) to the region where the pH is equal to their pI at which point they become electrically net neutral. Analytes remain focused into characteristic zones because any movement into the surrounding pH medium results in a net charge difference, an opposing mobility, and consequently a return to the region where the pH is equal to the analyte's pI. (d) Affinity electrophoresis is utilized to determine binding constants between ligands and receptors. In particular, the electrophoretic mobility of a protein varies with the occupancy of the binding site ligand and therefore changes in migration time are used to estimate interaction.

the opposite electrodes with their movement dependent on both charge and size (Figure 5a). Here, EOF is fundamental, allowing for the separation of positively charged, negatively charged, and neutral or uncharged species. However, situations may arise when EOF is undesirable and the inherent electrophoretic mobility of the protein of interest is of sufficient magnitude to reach the detector.

5.1.1 Proteins and Glycoproteins

The separating power of CZE has been demonstrated for a number of proteins. Early separations by Nielson et al.[48] highlight the utility of the technique for separation of the desamido and didesamido forms of human growth hormone (hGH). To limit protein–wall interactions, the pH was raised to 8.0, well above the pI of

the hGH which is 5.2. More recently, CZE with LIF detection has been used to separate and detect green fluorescent protein (GFP) and GFP antibody complexes. Using a bare silica capillary and a borate buffer (pH 8.5), Korf et al.[49] successfully separated the two forms of GFP (GFP-1 and GFP-2). Implementing CE/LIF, a six order of magnitude increase in detection sensitivity (over conventional methods) was achieved. This allowed for detection of GFP in the attomolar range. In addition, GFP was separated from GFP-complexed antibody. This presents the possibility of using CE for rapid screening of anti-GFP antibodies. Hiraoka et al.[50] demonstrated the utility of CZE for the rapid separation of β-trace protein (βTP), a low-molecular-weight protein synthesized in the central nervous system (CNS). βTP was clearly determined in all of the samples, and internal standard quantitation was possible using a allylamine. The results indicate that βTP is nonspecifically increased in organic diseases of the CNS, especially those associated with severe physical damage to the brain tissues (such as multiple sclerosis and cerebral infarction).

It was previously not appreciated that many proteins contained glycan structures, making them difficult to separate. Tiselius[1] offered proof of this complex structure showing that some proteins migrated as broad zones. Since then, the resolution of individual glycoforms has been achieved in several laboratories. Kilar and Hjérten[51] were among the first to report successful separation of glycoforms differing by a single charge. Using a static polyacrylamide coating and a buffer system composed of Tris/borate/EDTA (ethylenediaminetetraacetic acid) the glycoforms of purified transferrin (Tf) were resolved. Not long to follow were CE-based separations of the glycoprotein human erythropoietin (rHuEPO), whose primary function is to promote and stimulate the production of red blood cells. Tran et al.[52] experimented with various buffer systems, organic modifiers, and a variety of pH regions revealing the effects of optimal buffer selection for glycoform analysis using CE. This concept of condition optimization using additives or pH modification applied to the separation of a number of glycoproteins. Almost simultaneously, Landers et al.[53] and Traverna et al.[35] examined the utility of borate complexation with a diaminoalkane for the resolution of glycoprotein isoforms. Using 50 mM phosphate (pH 9.0) or 100 mM borate (pH 6–10) Landers et al.[54] partially separated five glycoforms of ovalbumin. Addition of diaminobutane (DAB) to the borate buffer (pH 8–9) appeared to slow the EOF and allowed for the resolution of 9–12 glycoforms in a purified preparation. Traverna et al.[35] found that recombinant tissue plasminogen activator (rtPA) glycoforms were poorly resolved in coated or bare silica capillaries using a 100 mM phosphate buffer (pH 3.6). In an effort to enhance the separation, DAB was added to a number of buffers at varying pHs to examine effects on glycoform resolution. The addition of DAB to a borate buffer (pH 8.5–10) was not effective for achieving improved resolution of the rtPA; however, a tricine–DAB buffer resulted in an improved separation. DAB was not efficient with the borate buffer because the highly sialyated glycoprotein cannot effectively complex with borate. This prevents the ionic borate–DAB interaction which appears to be necessary for the resolution of glycoforms. More recently, Watson and Yao[55] employed an uncoated capillary and a buffer containing 10 mM tricine/10 mM NaCl/2.5 mM DAB to partially resolve five peaks of erythropoietin. Addition of urea to the separation buffer allowed for the resolution of six peaks. The isoforms were identified by individually spiking with characterized sialoforms. Similar conditions to those employed by Landers et al.[53] were employed by Morbeck et al.[56] to separate the glycoforms of the hormone human chorionic gonadotropin (hCG). A 25 mM borate buffer containing 5 mM diaminopropane was used to separate the eight glycoforms of native hCG. The distribution of glycoforms was found to vary when hCG was purified from patients with choriocarcinoma, thus highlighting the potential of capillary electrophoretic separations for diagnostic and screening purposes. Although effective for resolving the complex heterogeneity of a number of glycoproteins, the mechanistic role of diaminoalkanes in improving the resolution of CE separations is still under investigation. Preliminary results indicate that the mechanism through which DAB and other similar additives effect resolution of glycoforms may involve more than slowing the EOF.[57,58]

5.1.2 Clinical Applications

As a result of its speed, efficiency and miserly use of reagents and sample, CE has begun to gain momentum as an acceptable analytical technique in the clinical laboratory for both routine and esoteric diagnostic analyses. For example, hemoglobin (Hb) analysis is important because mutations in the protein chains induce variations in structure and impair their oxygen carrying ability. Variants of Hb, typically detected by agarose and IEF gel electrophoresis, have been shown to be analyzed effectively with a single CE analysis. Ong et al.[59] were able to separate the components in hemolysates from normal individuals and those thought to have thalassemia. A high pH phosphate buffer was used to achieve separation of these proteins in less than 8 min. Klein and Jolliff[60] used a near-neutral buffer to separate globin variants A_2, A_1, A, S, and C. Under these conditions, dramatically different profiles were found for a number of Hbs. Others have used CE technology to analyze

purified globin chains in a substantially decreased time frame from that obtained using paper chromatography or HPLC. Both Ishioka et al.[61] and Ross et al.[62] have applied this approach to rapid screening of globin chain and Hb variants.

CE has also been shown to be applicable to the analysis of serum proteins. Since Chen et al.[63] proposed CZE as a viable alternative to agarose gel electrophoresis (AGE), a number of studies have been carried out showing the superiority of CE to conventional cellulose acetate electrophoresis (CAE) or AGE methods.[64–66] Clark et al.[67] and Katzmann et al.[68] compared the effectiveness of CAE, AGE, and CE for the detection of monoclonal proteins in serum. Using a bare silica capillary and borate buffer, separation was achieved in 120 s and clear differences in abnormal and normal monoclonal profiles were observed. Clark et al.[67] concluded that qualitative results obtained by CZE were comparable or better than those obtained using the gel electrophoresis counterpart. In particular, CE provided a clear advantage over gel techniques for determining the presence of a monoclonal protein for two reasons: first, precipitation is not a problem in CE and, second, in CE, the point of detection is unaffected by the point of injection. In comparison, Katzmann et al.[68] focused more on the quantitative aspects between AGE and CE. In this study, details concerning sensitivity, specificity, and quantitation were evaluated and discussed. Jolliff and Blessum[69] recently conducted a study comparing results of serum protein analysis by AGE and CE. It was determined that CE exhibited superior reproducibility over AGE methodology. This was attributed to protein detection using direct UV detection compared to conventional staining techniques. In a more comprehensive study conducted by Katzmann et al.[70] sera from more than 1300 patients was examined using both conventional AGE and CE (Figure 6). CE was superior to AGE for the detection of serum abnormalities including polyclonal increases in immunoglobulin, point of application artifacts, β-region abnormalities, and, finally, the presence of free light chains. In many instances, sera identified as normal using conventional techniques was shown by CE to be abnormal. More comprehensive overviews of serum protein analysis via CZE are available.[64,65,71–73]

In retrospect, serum protein analysis was an interesting challenge for CE in light of the complex nature of this matrix, the diverse character of the proteins, and their high concentration in serum. The high-pH approach (pH 9.8–10.2) works extremely well with serum where the serum sample can be injected neat (undiluted) without any sign of fouling the capillary. This is, no doubt, a function of the basic separation buffer as well as the between-run capillary regeneration with 1.0 M NaOH. Although there is a long-standing concern about the longevity and integrity of capillaries repeatedly exposed to these extreme conditions, the reproducible use of the same capillary for analysis of 20–30 serum samples daily for months without any indication of performance degradation has been observed. This speaks volumes for the ruggedness and robust nature of CE for the analysis of crude mixtures.

Figure 6 Detection and identification of monoclonal proteins by AGE and CE. An abnormal serum sample with a monoclonal peak in the γ-region (indicated by the arrow) was separated and analyzed using AGE and CE. AGE was performed on a Helena REP system using the REP SPE-30 agarose gels visualized with Ponceau S Stain. Peaks were calculated using the Helena ECD scanner and software designed for the multilane agarose clinical gels (Helena Laboratories, Beaumont, Texas). CE was performed on a Beckman Paragon CZE 2000 system using Beckman system buffers, the automated sample handling module and Beckman software designed for the seven-capillary clinical instrument (Beckman Instruments, Brea, California). Immunosubtraction (IS) was performed to determine the identity of the spike. Subtraction with anti-κ, anti-λ, and anti-IgG reagents removed the M-spike (panels b, c and d respectively). The anti-IgA and IgM (panels e and f) reagents had little effect. (Taken with permission from ref. 70.)

In addition, CE has been applied to the analysis of urine proteins. Urinalysis has wide clinical significance, particularly because abnormal patterns are seen in many pathological conditions including various renal disorders and light chain disease.[74–77] It was initially thought that urinary proteins, which originate from serum protein and have a similar pattern and distribution, could easily be analyzed by CE. However, a number of problems were encountered including interference from other compounds at the wavelength of detection, capillary overloading due to variability in sample protein concentration, and heterogeneous migration times. Early attempts by Chen et al.[78] to separate and identify urine proteins by CE involved the use of a dialysis membrane with a molecular mass cut-off at 14 kDa. The dialysate was electrophoresed using UV detection at 214 or 254 nm. However, a large number of peaks from small molecules and protein breakdown products were present. Jenkins et al.[79] evaluated the correlation between CE and high-resolution agarose gel electrophoresis (HRAGE) for the quantitation of Bence Jones protein (BJ) and albumin, both important in assessing patients with multiple myeloma. Using CE, identification and determination of migration times for a number of urine proteins was achieved. In addition, good correlation (0.93 for albumin and 0.95 for BJ) was found between CE and HRAGE. Shihabi[80] used CE to separate and quantitate myoglobin, a protein found in patients with disorders reflecting muscle tissue breakdown including burns and trauma infections. The analysis of myoglobin in urine appears simple but is difficult for two reasons: Hb, the main pigment protein in urine, can interfere with myoglobin detection; and myoglobin denatures rapidly (within a few hours) in urine. Using an uncoated capillary and a borate buffer, separation of myoglobin and Hb was achieved in less than 7 min. Similar to many CE analyses, addition of the buffer additive poly(ethylene glycol) improved the separation by providing a sieving matrix and limiting protein–wall interactions. Friedberg and Shihabi[81] also showed detection of urine proteins at 214 nm can be achieved by using either a wash step or cold ethanol precipitation to eliminate many interferences, whereas Oda et al.[82] demonstrated the utility of CE for identifying the presence of monoclonal proteins in urine. In a study of more than 200 patients, diagnostic information obtained by CE was comparable to AGE. More recently, Jenkins[83] demonstrated CE analysis of unconcentrated urine using a bare fused silica capillary where protein concentrations as low as 0.004 g L^{-1} could be detected (Figure 7). Under these conditions, BJ, intact immunoglobulin, and Tamm Horsfall protein, were separated and identified. In addition, electropherograms similar to those obtained using concentrated urine were obtained, thus eliminating the expense and time consumed for concentration procedures.

Figure 7 CZE separation of unconcentrated urine. Electrophoretic separation was carried out in a 72 cm × 50 µm fused silica capillary with buffer consisting of 150 mM boric acid (pH 7.5) and 1 mM calcium lactate. 40 µL of urine were diluted in 60 µL of buffer and vacuum injected for 5 s. (a) Detection of normal urine proteins urea, Tf and albumin. (b) Detection of four major urine proteins (0.04 g L^{-1}) including BJ. (Taken with permission from ref. 83.)

5.2 Capillary Gel Electrophoresis

Although one might expect that denaturing separations of proteins in sieving matrices should be easily extrapolated

from the gel format to the capillary, this has not been trivial. In fact, generating cross-linked polymer matrices or chemical gels (such as cross-linked polyacrylamide) in capillaries was difficult and suffered from technical and longevity problems. This inadequacy was solved with physical gels or pumpable polymer networks using polymers that were soluble, had low viscosity and were noncross-linked. The successful implementation of physical gels for use in DNA separations provided the format for denaturing protein analysis in capillaries. This involves standard heat denaturation of the protein sample in the presence of surfactant, such as sodium dodecyl sulfate (SDS), and separating in a sieving matrix such that separation is dependent on the molecular mass. Typically, the capillary is coated to eliminate EOF and is filled with a polymer sieving matrix buffer. The sample is then introduced either electrokinetically or via pressure injection under an applied electric field. As the proteins are SDS coated and hence negatively charged, they have anodic mobility and the separation must be carried out using reverse polarity (Figure 5b). CGE has begun to gain popularity for molecular weight determination of proteins but still possesses some limitations.

5.2.1 Denaturing Analysis of Proteins

SDS/PAGE (sodium dodecyl sulfate polyacrylamide gel electrophoresis) separation of proteins was first reported by Hjérten[84] who was able to separate human serum proteins using polyacrylamide as a sieving medium. Early work in this field was also carried out by Cohen and Karger[85] who demonstrated the utility of SDS/PAGE for separation of myoglobin fragments and a number standard proteins. These and other CGE separations were performed using cross-linked acrylamide as the chemical gel, which has been found to provide high resolution separation of low-molecular-weight biopolymers. However, several problems with the chemical gel-filled capillaries were realized. For instance, polyacrylamide absorbs at low-UV wavelengths, increasing the difficulty of high-sensitivity detection. Also, as a result of the rigidity of the gel, the lifetime of the capillary suffered. For example, Tsuji[86] found that, with a linear polyacrylamide gel-filled capillary, only a few runs were possible before the capillary had to be replaced. Although longevity was improved by the addition of ethylene glycol, the short capillary lifetime remains a major obstacle in implementing chemical gel-filled polymers for use in CE. Consequently, a search for a replacement for these permanent gels was undertaken.

Low-viscosity physical gels which are replaced after each run have become increasingly popular for CGE and can be used as noncross-linked polymer networks for the separation of high-molecular-weight SDS–protein complexes. Ganzler et al.[87] showed successful separation of SDS–protein complexes, ranging in molecular weight from 17 to 206 kDa using polymer networks and low-UV detection. With the polymer gel replaced after every run, a minimum of 300 separations were performed in the same capillary without a detectable loss in resolution. Shieh et al.[88] demonstrated the reproducibility and stability of capillary SDS–protein separations with seven protein mixtures that were separated in 15 min with less than 2% RSD (corrected migration time) in run-to-run and day-to-day reproducibility. Vecchione et al.[89] used denaturing CE conditions to separate platelet membranes from normal individuals and those with Glanzmann Thrombasthenia (GT), a hemorrhagic defect. In this study, the glycoproteins IIb and IIIa, which form heterodimers allowing for platelet–platelet cohesion, were analyzed. Using an eCAP SDS 14–200 fused silica capillary (Beckman) and reverse polarity, separation was achieved in less than 30 min. Healthy controls consistently showed the presence of glycoprotein IIb and IIIa, whereas these peaks were absent from electropherograms obtained from infected patients. Manabe et al.[90] employed linear polyacrylamide as a sieving matrix for separation of SDS-complexed plasma proteins. Here the effects of the buffer composition, concentration of the sieving matrix, and sample solution composition were examined. In addition, high-resolution size separation of SDS-complexed proteins was achieved. Major plasma proteins, including albumin, IgG, and Tf, were identified from their known molecular masses. Also, linear polyacrylamide capillary electrophoresis (LPA/CE) analysis of IgG myeloma sera revealed extremely high values of IgG, suggesting the methodology may be useful in screening serum samples. SDS/CGE is useful for the analysis of proteins with a large affinity for adsorption to surfaces. This has been demonstrated for the separation of fibronectin (FN), a cellular adhesion protein with a relative molecular mass (M_r) of about 400 kDa. Employing SDS denaturing conditions, the separation of FN from a series of protein standards was achieved (Figure 8).

The pharmaceutical/biotechnology industry was quick to recognize the potential for CE as a rapid quality control process. CE is especially attractive because it combines the quantification benefits of HPLC with the separating power of conventional gel techniques.[91,92] SDS/CGE has been compared to conventional gel SDS techniques (SDS/PAGE) for in-process control of antithrombin III (ATIII) and human clotting factor IX (FIX). In the case of ATIII, SDS/CE showed results comparable with conventional techniques with the advantage of a shorter analysis time. SDS/CGE also gave similar results for FIX but was less sensitive for detection of low-concentration proteins.

Figure 8 Denaturing SDS/CE. Electrophoretic separation was carried out in a 37 cm × 100 μm acrylamide coated capillary with gel buffer consisting of 1% SDS and 5% ethylene glycol at 14.1 kV with reverse polarity. Denatured FN in 1% SDS and 1% Trizma [tris(hydroxymethyl)aminomethane] was injected for 30 s. (a) Separation of molecular weight standards: 1 = Orange G, reference marker; 2 = α-lactalbumin, 14.2 kDa; 3 = carbonic anhydrase, 29 kDa; 4 = ovalbumin, 45 kDa; 5 = bovine serum albumin, 66 kDa; 6 = phosphorylase b, 97.4 kDa; 7 = β-galactosidase, 116 kDa; 8 = myosin, 210 kDa. The inset is a plot of log molecular weight versus inverse of relative migration time. The regression equation is $y = -26.035x + 3.908$, with $r^2 = 0.994$. (b) The separation of 1 mg mL^{-1} of FN (19.5 min) and dual injected standards. The calculated molecular weight for plasma FN based on the standard curve given in the inset of (a) is 374 kDa.

5.2.2 Nondenaturing Gel-based Analyses

In addition to denaturing protein separations, CGE can also be utilized for nondenaturing protein separations. For instance, Oda et al.[93] and Prasad et al.[94] have developed a separation method using borate buffer with a cellulose-based sieving matrix to allow for baseline resolution of Tf glycoforms. Of particular interest to these researchers is a region known to contain carbohydrate deficient transferrin (CDTf), Tf containing less sialic acid (and carbohydrate) than the tetrasialotransferrin found as a dominant form in normal individuals. The serum Tf glycoform distribution is affected by a number of pathological states. Included in these are carbohydrate deficient glycoprotein syndrome (CDGS), a pathological condition where the cellular machinery for protein glycosylation is defective. This disease manifests itself as a neurological disorder and is characterized by an increase in the CDTf (which is composed of the di-, mono-, and asialoforms) level. Chronic, excessive alcohol abuse has also been linked to an increase in CDTf levels in serum and, therefore, presents the possibility of monitoring excessive alcohol abuse using this methodology.[95] More recently, Trout et al.[96] have improved this assay for the analysis of CDTf in neat serum, circumventing the need for immunopurification. Using an FC-coated capillary to slow EOF and a borate buffer system, Tf sialoforms are resolved with the direct injection of diluted serum, allowing for resolution and identification of both normal and abnormal (alcoholic) Tf glycoform patterns (Figure 9). This presents the possibility for the rapid testing of compliance in both alcohol treatment and liver transplant clinics.

It is important to bear in mind that results obtained with the use of physical gel-filled capillaries can be influenced by capillary temperature. Guttman et al.[97] found dramatically different temperature effects with two different sieving matrices, poly(ethylene oxide) (PEO) and dextran. At elevated temperatures dextran chains are able to orient, through polymer–polymer interaction, into channel-like structures which yielded better resolution compared to that achieved at room temperature. The opposite effect was observed with PEO.

5.2.3 Ferguson Plots

Proteins undergoing post-translational modification, such as the addition of carbohydrates or lipids, do not bind SDS in the same ratio observed with unmodified proteins (1.4 g SDS per gram of protein). Consequently, gel-based molecular weight determination is often inaccurate due the lower charge to mass ratios, i.e. the molecular mass is overestimated. Ferguson[98] developed a method to correct for the variability in SDS binding which involves determining the mobilities of standard proteins

Figure 9 Separation of (a) normal and (b) alcoholic human serum Tf using CZE. Using an FC-coated capillary (J & W Scientific) and a buffer containing a polymer sieving matrix (0.5% hydroxyethyl cellulose) separation of Tf glycoforms is achieved in less than 25 min. The nonalcoholic serum profile has normal concentrations of the sialoforms in the CDTf region. In comparison, elevated concentrations of the disialoform and the presence of asialo-Tf are seen in the alcoholic profile. The peaks are 0, asialoform; 2, disialoform; 3, trisialoform; 4, tetrasialoform.

at several different gel concentrations. The slope of an initial plot of the log of reciprocal migration time versus gel concentration gives the negative of the retardation coefficient k_r. A second plot (log molecular weight as a function of k_r) yields a more universal calibration curve. Performing Ferguson analysis using multiple slab gels at different acrylamide concentrations has obvious disadvantages – the advantage of translating this analysis to CE with replaceable gels and an automated format is clear. Werner et al.[99] demonstrated this with a variety of proteins including α-lactalbumin. In most cases, Ferguson plots yielded better molecular weight estimates than SDS/PAGE. It is important to remember, however, that although abnormal charge-to-mass ratios are accounted for, abnormal protein shapes are not.

5.3 Capillary Isoelectric Focusing

IEF is an equilibrium protein separation technique that relies on the establishment of a pH gradient in the gel. Unlike density gradient centrifugation and gradient gel electrophoresis, which separate based on size or density, IEF separates molecules based on their pI. By establishing a pH gradient, molecules will migrate to the zone at which the pH is equal to their pI, i.e. their net charge is zero (Figure 5c). If diffusion occurs to any extent, the molecule enters a region with a different pH resulting in the analyte acquiring a charge and electromigrating back into the focused zone. As a result of a mechanism where electrophoretic migration counters diffusional effects (as long as voltage is applied to the system), IEF has enormous resolving power.

The analysis of polypeptides has been the most prominent application of this focusing technique, particularly for determining pIs of proteins, characterizing biological fluids and monitoring protein purification. IEF has also been exploited for the analysis of glycoform microheterogeneity and resolution of charge variants.

5.3.1 Technical Considerations

Consideration of the sample matrix is an integral component in developing CIEF methods. Attention must then be paid to selection of appropriate ampholytes, adjustment of salt concentration, and dilution or concentration of the protein sample if necessary.

Broad-range ampholytes (pH 3–10) are generally used for protein mixtures with a wide spectrum of pIs, whereas narrow-range ampholytes (pH 5–8) are utilized to achieve increased resolution. It is unfortunate that the very mechanism of separation (an ampholyte-based pH gradient) masquerades as one of the obstacles in CIEF protein separations. Specifically, ampholytes (essentially polypeptides) absorb UV radiation at 200 nm which, for protein separations, is the ideal wavelength of detection. Consequently, CIEF requires detection at 254 or 280 nm which results in a substantial decrease in sensitivity for protein analyses.

With respect to salt concentration, several problems are encountered when the sample salt concentration is too high. For example, increased current due to high ionic strength, loss of resolution and gradient compression during focusing are all complications associated with high salt concentration. Consequently, samples with salt concentrations higher than 50 mM should be desalted by dialysis, gel filtration or ultrafiltration prior to focusing. A companion problem associated with high sample concentrations is protein precipitation, which is a combined function of the high protein concentrations used in CIEF and the decreased solubility of individual proteins at their pI. For example, in addition to capillary occlusion, protein precipitation can result in irreproducible migration times, current instability and slow mobilization. To counteract these consequences, detergents such as urea are often employed as additives to increase the solubility of proteins. Nonionic detergents including Triton® X-100 and Nonidet P-40, and zwitterionic detergents such as CHAPS (3-[(3-cholamidopropyl)dimethylammonio]-1-propane sulfonate) are the most commonly employed solubilizing agents.[100]

To detect the protein zones, mobilization past the detector must be initiated. This can be achieved in a number of ways. Single-step CIEF uses EOF to transport the focused zones past the detector. Although EOF mobilization allows for more rapid analysis times than the two-step method, the loss of resolution and complications in relating the migration time to the pI have resulted in the two-step method remaining the most common approach to CIEF. In two-step CIEF, the protein bands are focused to steady state as described earlier. Coated capillaries are used to reduce the magnitude of the EOF so that the zones are not mobilized prior to the completion of focusing. Transport of the focused zones by the detector can then be performed by several different mechanisms including chemical and hydraulic mobilization. In chemical mobilization, the application of voltage is terminated after focusing is complete and the analyte or catholyte is replaced with mobilization reagent. An electric field is reapplied to facilitate mobilization. Neutral salts, such as sodium chloride, are the most common means of achieving chemical mobilization. Sodium serves as the nonproton cation in anodic mobilization and chloride as the nonhydroxyl anion in cathodic mobilization.[101]

An alternative is hydraulic mobilization which utilizes the application of pressure[102] or vacuum[103] to mobilize the focused protein zones past the detector. It is necessary to apply an electric field to the capillary simultaneously to decrease the diffusion of the protein zones and, hence, loss of resolution during hydraulic mobilization. The disadvantage of using this method of mobilization is that the parabolic shape of the hydrodynamic flow can decrease resolution. To minimize this effect, only weak forces are used. Chemical mobilization generally produces sharper peaks for the basic proteins whereas hydraulic mobilization increases the efficiency of mobilizing acidic proteins. In addition, chemical mobilization provides much better linearity when plotting migration time versus pI, as well as better reproducibility than its hydraulic counterpart.

5.3.2 Protein Isoelectric Focusing in Capillaries

CIEF is useful for analyzing proteins that, due to amino acid mutation, post-translational modification, or the binding of metals, have extremely small differences in pI. For example, CIEF has been utilized to resolve HbA (adult hemoglobin) and HbF (fetal hemoglobin) as well as abnormal Hb variants differing only by a single point mutation in the Hb gene. Zhu et al.[104] as well as other groups[105,106] demonstrated the separation of Hb A and F, and variants S and C (associated with various thalassemias). Although analysis times were somewhat lengthy (approximately 13 min), remarkable resolution of the globin chains was achieved. With an unorthodox approach, Yowell et al.[105] showed promising results focusing protein at the detector end of the capillary, significantly reducing the analysis time. In addition, Zhu et al.[107] also showed the utility of CIEF for separation of Hb G Philadelphia and Hb C, two Hb variants associated with Bart's disease, another potentially lethal hematological disorder. Hempe and Carver[106] examined CIEF for use in Hb-variant screening. Using conditions that provided separation in less than 15 min for rapid turnaround times in a clinical setting, they obtained quantitative data on Hb variants and identified several rare Hb types using CIEF. The quantitative results agreed well with conventional methods, thus confirming the utility of CIEF for routine assays. Hempe et al.[108] recently improved this assay by limiting capillary exposure to NaOH, consequently increasing capillary lifetime. In addition, improvements in the between-run reproducibility (9.6% RSD using the original method) enhance the quantitation precision. Using this novel methodology, diagnosis of HB s/β^+ thalassemia is possible in one analysis (Figure 10). Conventional clinical analysis methods would require at least three separate assays to make the same interpretation.

CIEF has also has been exploited for the separation and characterization of monoclonal antibodies. These biomolecules are challenging to separate as a consequence of their large size, tendency to aggregate, and heterogeneity due to post-translational modifications. Analysis of monoclonal antibodies including recombinant

Figure 10 Separation of Hb variants using CIEF. Electrophoretic separation was carried out in a 27 cm × 50 μm DB-1 capillary (J & W Scientific) at 30 kV. Hydraulic mobilization was employed. Hemolysate was introduced by low pressure injection (3.5 kPa) for 10–30 s. (a) Abnormal control formulated to resemble blood with the sickle cell trait (HbS) and HbA_2 (observed in patients with β-thalassemia). (b) A blood sample from a patient with HB S/β^+ thalassemia. High-efficiency separation is necessary for identification of the underlying double heterozygous. Here elevated HbA_2 helps differentiate potential causes of elevated red blood cell count (RBC), low Hb concentration and low mean corpuscular volume (MCV). (Taken with permission from ref. 108.)

ATIII[109] and recombinant humanized monoclonal antibody HER2,[110] which are significant in the diagnosis of certain types of cancer, has become possible using CIEF techniques.

Kilár et al.[111] have developed a unique set-up for CIEF in uncoated capillaries. With this approach, a sandwich technique is employed where the ampholytes and analytes are injected in three steps: ampholyte solution, sample, and ampholyte solution. This allows for the use of homolog or heterolog (containing both broad and narrow range) ampholytes to be used. Also possible use of the sandwich approach is the detection of proteins with pI values outside the ampholyte range. The methodology was used for separation of Hb variants from normal and diabetic patients (Figure 11). The results obtained were similar to those using other conventional techniques.

5.3.3 Glycoproteins

Another important application of CIEF methodology is its utility for interrogating glycoform microheterogeneity. Glycoproteins often display microheterogeneity as a result of qualitative and quantitative differences in the location, length and content of the carbohydrate moieties linked to the polypeptide. This becomes important not only for understanding the function of microheterogeneity in biological systems, but also in monitoring the glycosylation pattern in the development and production of protein therapeutics. CIEF has been shown to be an excellent automated and quantitative method for analysis of glycoforms when detection sensitivity is not a critical issue. An example of the potential of this application is the analysis of human rtPA, a protein that degrades blood clots and is manufactured for treatment of myocardial infarction.[112–115] Although purification of rtPA is required for high-purity IEF, in some cases as many as 20 peaks persist. However, neuraminidase treatment simplifies the pattern, suggesting that the heterogeneity may be attributed to varied sialylation.[112] In addition, analysis of human Tf isoforms is possible using IEF. Kilár and Hjérten[116] successfully resolved the Tf glycoforms from normal individuals showing the expected di-, tri-, tetra-, penta-, and hexasialoforms. Also, Wu and Pawliszyn[117] implemented IEF methodology to examine changes in the pI of Tf due to iron binding.

5.4 Affinity Electrophoresis

Affinity capillary electrophoresis (ACE) refers to the analysis of general ligand–receptor interactions and can be used to (1) determine which sample components might undergo specific complexation, (2) investigate conditions surrounding this formation, and (3) quantitatively study

Figure 11 Novel CIEF methodology for the analysis of Hb variants. Electrophoretic separation was carried out in a 67 cm × 50 μm bare silica capillary at 20 kV. Single-step mobilization was employed with a 10 mM phosphoric acid analyte and a 20 mM sodium hydroxide catholyte. A heterologue ampholyte solution was employed using both a narrow (pH 6.7–7.7) and broad (pH 3.5–10) pH range. (a) Hb variant control (Isolab) solution (1 mg mL^{-1}). (b) Hb from a normal adult (1 mg mL^{-1}). (c) Hb from a diabetic patient (1 mg mL^{-1}). (Modified with permission from ref. 111.)

the complex. ACE can therefore be used to provide both qualitative and quantitative information about molecular interactions. This is possible because the electrophoretic mobility of a free protein changes upon binding with a ligand present in the electrophoresis buffer (Figure 5d). The difference in mobility is attributed to changes in charge, conformation, or both. Thus, by measuring the migration time of the complex as a function of ligand concentration the equilibrium constant may be calculated.

Classical gel methods may be employed to study these characteristics. However, they often require the

use of radio-labeled, fluorescently labeled, or secondary reagents that can be costly and difficult to use. In contrast, the capillary format does not demand purification of receptors and requires only small amounts of sample for analysis. As a result, the binding constants for the interaction of several receptors with their respective ligands can be determined simultaneously. Other advantages of the capillary format include temperature control, free solution separations and high-speed analysis.

5.4.1 Proteins and Glycoproteins

The utility of CE for determination of binding constants was realized when the first paper describing the use of CE for protein analysis appeared in 1986. As mentioned previously, Lauer and McManigill[118] found that protein migration times were retarded due to ionic interaction with the capillary wall. Thus, as many of the binding forces between proteins and ligands are ionic in nature, it was obvious these interactions could like-wise be examined. Consequently, two approaches for measuring binding constants using CE emerged – nonequilibrium and equilibrium methods. The latter of the two, commonly termed ACE, will be discussed briefly here. A comprehensive treatment of the subject is given by a number of published reviews on the subject.[119–121]

ACE is an ideal technique for examining the binding of metal ions to metal-binding proteins. This results from the fact that minute changes in the charge of the protein will effect the electrophoretic mobility and, consequently, the migration time. Heegard and Robey[122] examined the effects of Ca^{2+} concentration on the migration time of human C-reactive protein (CRP). They observed the expected decrease in mobility with increased ion concentration. Similar results were obtained by Kajiwara et al.[123] using the proteins calmodulin and parvalbumin.

Protein–protein interactions can also be studied using CE techniques. Early work by Grossman et al.[124] showed separation of antibody–antigen complexes using CE. Nielsen et al.[125] extended these findings by separating free hGH and antibody from the hGH–antibody complex. Although protein–protein measurements (as a result of their size) can be accomplished by a host of other techniques which are equal or superior to ACE, this technology offers advantages when the proteins of interest are present in limited quantities.

A diagnostic test for the scrapie prion protein (PrP^{SC}), a transmissible spongiform encephalopathy (TSE) found in sheep and goats which causes progressive degenerative disorders to the CNS, has been designed using CE competitive immunoassay.[126] Here CZE with LIF was used to detect the fluorescein-labeled peptides from PrP^{SC}. Antibodies for each peptide were used and antibody-bound peptides were separated from unbound peptides. Using PrP^{SC} extracted from infected sheep, detection of 135 pg of PrP^{SC} was possible. However, protein extracted from normal sheep did not compete for bound peptides, indicating absence of the antigen. Another clinical application of ACE involves the investigation of the epitope on the human immunodeficiency virus (HIV) recognized by a monoclonal antibody.[127] Antibodies to the protein p24 are among the first to appear in individuals infected with HIV.[128–131] In fact, the presence of this antibody is used as a screen for HIV in blood samples.[132–134] A correlation between a decreased level of p24 antibodies and the progression of HIV to full blown AIDS has been determined.[135–137] Consequently, an investigation of elements eliciting antibodies to p24 may be useful in developing an HIV vaccine. Previous excision-mass spectrometry (MS) experiments determined the epitope sequence of HIV p24 to be ^{102}HPVHAGPIAPG^{112}.[138] Using the ACE methodology, Qian and Tomer[127] identified two other sequences which exhibited weaker binding. These interactions were later characterized as nonspecific. However, a strong affinity of the antibody was found with the peptide VHPVHAGPIAP.

6 CONCLUDING REMARKS

Although only a fraction of the literature associated with the use of CE for protein analysis has been covered here, the growing acceptance of capillary-based analysis as an alternative to the conventional slab and tube gel formats, and as a complementary technique to HPLC, is clear. The advantages driving the interest in this technology include the simplicity of a system that can provide electrophoretic protein analysis in free solution, with multimode capabilities, minimal reagent and sample requirements, high efficiencies, on-line detection, and all in an automated format. This allows for rapid definition of optimal conditions as well as experimentation with numerous modes in search of a suitable method for a particular protein(s).

Unlike other analytes, the CE-based analysis of proteins is complicated by the predisposition of these solutes for adsorption to the capillary wall. One must, therefore, be prepared to seek a compromise between conditions ideal for the stability of the protein(s) of interest and those which minimize adsorption, so that separation efficiency is not destroyed. Capillary wall deactivation can be accomplished using a battery of approaches including covalent modification of the surface as well as dynamic deactivation. The latter is a largely

unexploited area that warrants exploration based on the simplicity of surface passivation via simple modification of the separation buffer.

It is clear that the same multimode flexibility associated with protein analysis by gel electrophoresis and HPLC is applicable to CE. Consequently, the simplicity of CE will allow for accelerated method development for applications ranging from purity characterization and microheterogeneity analysis to pI determination and clinical marker detection. As methods for protein analysis evolve, one can expect to see the development of protein CE buffer systems with improved compatibility for detectors such as MS. This will facilitate the use of hyphenated techniques such as (CE/MS),[139] where CE is used as the first dimension with MS as the detector, and improve capabilities for structural identification and, ultimately, the establishment of functional properties of individual proteins and glycoproteins. The future will also see other hyphenated techniques furthered in their development where the speed of CE allows it to function as the second dimension. The pioneering work of Jorgenson's group with the development of liquid chromatography/capillary electrophoresis (LC/CE)[140] presents the possibility of revolutionizing protein analysis, especially if the two-dimensional system can be interfaced with MS as the detector. Technological advances such as these, combined with advances in method development, including capillary coating and detection, are sure to make protein analysis by CE commonplace in the future.

ABBREVIATIONS AND ACRONYMS

ACE	Affinity Capillary Electrophoresis
AGE	Agarose Gel Electrophoresis
ATIII	Antithrombin III
BJ	Bence Jones Protein
CAE	Cellulose Acetate Electrophoresis
CDGS	Carbohydrate Deficient Glycoprotein Syndrome
CDTf	Carbohydrate Deficient Transferrin
CE	Capillary Electrophoresis
CGE	Capillary Gel Electrophoresis
CIEF	Capillary Isoelectric Focusing
CITP	Capillary Isotachophoresis
CNS	Central Nervous System
CRP	C-reactive Protein
CTAB	Cetyltrimethylammonium Bromide
CZE	Capillary Zone Electrophoresis
DAB	Diaminobutane
EDTA	Ethylenediaminetetraacetic Acid

The focus of this article is to describe the developments of capillary electrophoresis (CE) on-line with detection by mass spectrometry (MS) for the analysis of peptides and proteins. Following a brief introduction in which we discuss the increasing role of the mass spectrometer for characterizing these important biomolecules, we present a historical overview of capillary electrophoresis/mass spectrometry (CE/MS). The latter discussion describes the experiments that allowed the connection of CE with MS, through developments to increase the volumes of analyte solutions that can be analyzed, to the current investigations of microfabricated chips that bring CE/MS towards a nanoscale technology. We also consider the technical aspects of CE/MS, which include how to inject analyte mixtures into the capillary, ways to improve the concentration sensitivity of the technique, the optimal capillary surface technology to use, and considerations of buffer compositions that are compatible with on-line MS detection. Other practical issues, including the physical connection between the CE and MS components, along with sample preparation and sequencing peptides by this technology are also reviewed. In the final section, the future of CE/MS is contemplated, with particular emphasis on the current developments of nanotechnologies that include the interfacing of microchip-based CE with MS.

1 INTRODUCTION

The use of MS in the biomedical sciences has experienced rapid growth in recent years. This can be attributed to the development of technology [such as electrospray ionization (ESI)] that allows the rapid and cost-effective analysis of many thermally labile, hydrophilic molecules. Protein analysis, peptide mapping, and peptide sequencing at concentrations compatible with extracted amounts from biological systems by MS is a current area of continuous improvement.[1] This has accelerated developments in proteomic research, in which proteinaceous products of expressed genes are rapidly mapped.

Many MS strategies are evolving for sequencing of peptides and proteins. These include the use of micro- and nanospray technologies that allow low-flow infusion of analyte mixtures, and a more efficient utilization of precious samples.[2,3] This overcomes one of the main limitations of the scanning mass spectrometer, which is the acquisition of acceptable ion statistics for compounds of low transience in the instrument. High scan speeds usually correlate with reduced MS sensitivity. Prolonged persistence of molecules of interest within the mass spectrometer permits the use of slower scan speeds and a concomitant increase in sensitivity is observed. However, these techniques are not without limitations. In particular, ion suppression results in the detection of one species in preference to another. An inability to detect and characterize an analyte of interest (e.g. a phosphorylated peptide) may result when such molecule is a minor component of a complex mixture. This situation can often be overcome by separation of the components of the analyte mixture using chromatography on-line

with the mass spectrometer. In this regard, the coupling of condensed phase chromatography [high-performance liquid chromatography (HPLC) and CE] to the mass spectrometer has been thoroughly investigated and developments have occurred to provide technologies for the analysis of many widely different complex samples.[4,5]

In this article we present and review the techniques of on-line CE/MS for the analysis of peptides and proteins. Particular emphasis will be placed upon the developments that improve the robustness and sensitivity of this technology. We also review strategies that facilitate on-line manipulation of samples to effect isolation, concentration, and analysis of components of interest.

2 HISTORY

Characterized by fast analysis times, unrivalled analyte resolution and ultrahigh separation efficiencies, CE was expected to revolutionize the analysis of complex solutions of peptides and proteins.[6] Indeed, these characteristics along with low sample consumption and in theory improved analyte recovery (and thus high sensitivity) combine to yield a very powerful analytical technology, which was further enhanced through its coupling to the mass spectrometer.[7–10] Furthermore, CE offers a number of different separation mechanisms that complement traditional technologies such as HPLC. In addition to free solution separations, CE affords analyte resolution by isoelectric focusing,[11–15] isotachophoresis,[16] molecular weight sieving,[17] and even separation according to analyte hydrophobicity by interactions with micelles [as in micellar electrokinetic chromatography (MEKC)].[18] Affinity capillary electrophoresis (ACE)[19] and affinity capillary electrophoresis/mass spectrometry (ACE/MS)[20–24] separations have also been developed to investigate ligand–receptor interactions, and the potential for such technology for screening combinatorial drug candidate libraries has been demonstrated. However, the development of CE and on-line CE/MS for the analysis of peptides and proteins has not been without complex challenges, and these technologies have been shown to suffer some severe limitations. First, highest analyte resolution is usually only achieved when the sample injection volume is less than 2% of the total capillary volume.[25,26] Hence sample injection volumes are usually in the range of tens of nanoliters for regularly used capillaries [50 μm internal diameter (ID)][27] to low picoliters for small internal diameter capillaries (<10 μm ID)[28] that have been shown to yield the best CE/MS sensitivity. The concentration sensitivity of CE (and CE/MS) is therefore significantly inferior to that of other techniques such as HPLC, which can accommodate sample injection volumes of tens to hundreds of microliters.[4] Sample concentrations for CE and CE/MS analysis are thus often required to be exceptionally high. Typically, this is not ideal for mixtures of biologically important peptides and proteins. At high concentration, these molecules tend to denature, aggregate, and precipitate. Peptides and proteins also tend to adhere to surfaces of vials and pipet tips, which can lead to further substantial losses. Therefore, various creative approaches have been developed to enable the injection of larger sample volumes into the CE capillary. These include in-capillary electrophoretic analyte stacking[29–34] and focusing,[35–46] coupled capillary isotachophoresis (cITP) with CE,[47–49] and various designs of analyte concentrator[25,26,50–82] and membrane preconcentration (mPC) preprocessors,[83–96] and all of these approaches will be discussed later.

A second significant problem with CE (and CE/MS) arises from the fact that the silica surface of CE capillaries is not chemically inert. When filled with an aqueous solution, the silica surface takes on a negative charge that is dependent upon the pH of this solution.[97] This is one of the primary contributors to the development of an electroosmotic flow (EOF) from anode to cathode. However, such anionic character also provides an active surface for, in particular, basic peptides and proteins to adsorb. In addition to these electrostatic interactions, hydrophobic interactions and the formation of hydrogen bonds between the peptide or protein and the silica capillary are also prevalent. Hence, while there are no solid particles for analytes to adsorb irreversibly, peptides and proteins are often lost to the silica surface of the CE capillary.[98–100] Consequently, method sensitivity is reduced, as are analyte resolution and separation efficiency. Again, creative solutions have been developed to overcome this limitation. These include the use of buffers of extremes of pH, to suppress the ionization of the silica surface (low pH),[101] which has been successfully used for the analysis of peptides,[102] or to ensure that analytes are anionic (high pH).[103] Various capillary coatings have also been developed and several polymeric capillaries have been evaluated.[104] All of these approaches will be reviewed later.

The coupling of CE on-line with MS has also not been without challenge. Here, the technology had to be considered as a whole, since the predominantly aqueous buffer used for the CE separation has been shown to influence directly the MS performance and overall method sensitivity.[105,106] In addition, the interface between the CE and MS systems requires careful thought since this device has to provide both the counter electrode for the CE separation and the voltage (or ground) for the electrospray interface. While there have been a number of CE/MS interface configurations, one of the most popular is the sheath liquid interface that was first described by Smith et al.[7,8] This interface is readily assembled,

and is reasonably robust.[107] One limitation of this approach is that the sheath liquid can introduce a sizable chemical background. Miniaturization of the sheath liquid interface, so that the coaxially delivered sheath liquid is delivered at a flow rate of less than $1\,\mu L\,min^{-1}$, reduces such a background, and leads to a significantly improved signal-to-noise ratio (S/N).[108] Subsequently, development of a sheathless interface and the coupling of CE to micro- and nanospray MS has further improved the analyte sensitivity and S/N.[82,96,109–113] The coupling of micro-fabricated CE chips to MS in which the interface is a ''pin-hole'' in the side of the CE chip has also recently been evaluated.[109,114,115] These devices show much promise for the further development of this technology for high sensitivity analysis of peptides and proteins, and they are reviewed in a later section.

3 CONSIDERATIONS FOR CAPILLARY ELECTROPHORESIS SEPARATIONS OF PEPTIDES AND PROTEINS

3.1 Sample Injection

Three modes of sample injection into the CE capillary are typically used for analyte analysis by CE with on-line MS detection. These include electrokinetic injection, during which high voltage is applied to the sample solution; analytes migrate into the capillary according to their electrophoretic mobility, and may be transported by the migration of solvated ions.[116] This mode of injection is dramatically affected by the salt concentration of the sample matrix. The amount of analyte injected into the capillary can vary from sample to sample unless much care is taken to ensure that each sample is isotonic. Furthermore, analytes of differing charge will migrate into the capillary at different rates. Hence, this technique introduces selectivity into the analysis. For these reasons, electrokinetic injection is not usually particularly useful for the analysis of biologically derived mixtures of peptides and proteins.

The two other sample injection modes for CE/MS are based upon hydrodynamic flow. For one of these methods, the inlet of the CE capillary is immersed in the sample vial and raised, for a specific period, to a defined height above its outlet.[116] The volume of sample injected is dependent upon the back-pressure of the capillary, the height differential between the capillary inlet and outlet, and the time of the injection. This technique is often most commonly used when a home-made CE system is connected to the mass spectrometer. For commercially available units, the CE capillary is inserted into a sealed sample vial, to which a nitrogen head pressure is applied for a specific length of time. Sample is forced from its vial into the CE capillary, in preparation for subsequent electrophoretic separation. Since both of these techniques are based upon hydrodynamic flow, all components of a complex mixture are injected into the CE capillary and there is less selectivity than observed with electrokinetic injections. However, salt from the matrix of biologically derived samples will be introduced along with analytes of interest into the capillary. This will significantly affect the performance characteristics of the separation, and this subject will be addressed in the sections that follow.

3.2 Concentration Sensitivity

Many factors affect the overall sensitivity of CE/MS. One such factor is the design of the interface and the actual coupling of the two techniques. There is also an incompatibility of the peak widths of CE responses and the scan speed of the mass spectrometer. As mentioned above, faster mass spectrometer scan speeds typically result in reduced sensitivity of the scanning mass spectrometer. This problem has been overcome using one of several methodologies. First, if the analyte is known, selected ion monitoring (SIM) can be used to continuously monitor the compound(s) of interest.[5] Second, the type of MS detector can also play a role. For example, an array detector for a sector mass spectrometer can yield 50–100-fold more signal than a standard electron (or photon) multiplier.[117] Reduced elution speed (RES), in which the CE voltage is substantially reduced prior to elution of the first analyte, has been developed by Smith's group to widen CE peaks, thereby allowing the use of slower scan speeds.[118] Separations of proteins by cITP have also been coupled with MS.[46] This separation technique produces zones of constant protein concentration that are eluted into the mass spectrometer. This compares with a peaked response for most other separation techniques. Improved ion statistics may result. However, the development of cITP separation conditions is not as simple as free solution conditions, since buffer zones of different mobility are required to effect analyte resolution by the cITP mechanism.[16,49] Ion trap mass spectrometry (ITMS) (quadrupole traps)[112] and Fourier transform mass spectrometry (FTMS) (ion cyclotron resonance)[119] instruments and fast scanning time-of-flight (TOF) systems[120] may also afford improved sensitivity of CE/MS analyses (see later discussions).

The composition of the separation buffer (or electrolyte) and the ID of the CE capillary also affect the overall sensitivity of the CE/MS method.[104,105] A highly conductive background electrolyte (BGE) may be used for efficient CE separations but often interferes with electrospray processes, which can lead to reduced mass spectrometer sensitivity and ion beam instabilities. In this regard, it has been shown that the smaller bore capillaries

(<10 μm ID) lead to the highest CE/MS sensitivity.[28,121] The lower flow of BGE from these capillaries enables a wider variety of aqueous solutions to be used to effect analyte separations.[28] However, the use of small-bore capillaries also exaggerates the problem of poor CE and CE/MS concentration sensitivity. Such capillaries accommodate CE analyses of only very low volumes (often low picoliters) of sample.[25–27]

The low internal volume of CE capillaries leads to a requirement for high analyte concentration for all CE and CE/MS studies. Analyte preconcentration can be achieved by off-line sample preparation, using lyophilization, or adsorption on a solid phase to permit both sample cleanup and analyte concentration. However, off-line manipulations of dilute solutions of peptides and proteins should be minimized, since losses to exposed surfaces (e.g. vials, pipet tips, solid phases) can be substantial. In addition the tendency for these molecules to denature, aggregate, and, ultimately, precipitate causes further analyte losses. Therefore, many investigators have attempted to improve the sample loading capacity of the CE capillary while maintaining optimal analyte resolution and separation efficiency.

Initially, a variety of electrophoretic concentration techniques, including analyte stacking,[29–34] field amplification[35–45] and transient isotachophoresis (tITP)[46–49] were developed to preconcentrate analytes following injection of the sample into the capillary. All of these techniques are implemented as voltage is applied across the CE capillary, and cause analyte zones to concentrate owing to different field strengths or chemical microenvironments that form within the CE capillary.[116] Consequently, larger analyte volumes can be analyzed with minimal loss of component resolution and separation efficiency. In most favorable cases, the sample can constitute up to approximately 90% of the total CE capillary volume with minimal loss of CE performance. However, since the total capillary volume is small, maximum sample loading is usually limited to less than 1 μL. Furthermore, as mentioned above, salts in the sample matrix can disrupt such analyte stacking and focusing processes. Such matrix components introduce zones of low electric field within the capillary upon application of high voltage.[27,116] Analyte ion migration velocities are slower, and this usually prevents the analytes focusing into discrete zones. Therefore, preprocessing of biologically derived mixtures may be required to reduce their salt concentration prior to use of these electrophoretic stacking and focusing techniques. Nevertheless, use of in particular capillary electrophoresis/transient isotachophoresis/mass spectrometry (CE/tITP/MS) has provided a means for analyte preconcentration to a sufficient level to allow its use for the analysis of peptide and protein mixtures.[46]

A technique that emerged from single-column tITP was the use of coupled capillary isotachophoresis/capillary electrophoresis/mass spectrometry (cITP/CE/MS).[47–49] For this approach, cITP separations are performed in wide-bore (100–200 μm ID), larger volume capillaries. Following the cITP step, analytes are transferred into the CE capillary for further separation and subsequent MS detection. This technique permits the analysis of sample volumes as large as 20 μL, and as such it provides a practical means of enhancing the concentration sensitivity of CE/MS. However, this technique is significantly more complex than other strategies for concentration sensitivity enhancement, and is not particularly well suited to routine operation.

In another approach, capillary isoelectric focusing/mass spectrometry (cIEF/MS) allows the analysis of a full capillary volume of sample.[11–15,108,122,123] This technique has proved to be particularly useful for the analysis of complex mixtures of proteins. Separations are usually performed in a coated capillary that exhibits negligible or zero EOF.[15,108,122,123] In a focusing step, ampholites, which are premixed with the sample, migrate through the capillary to form a pH gradient. Simultaneously, proteins migrate until they reach the pH zone that corresponds to their isoelectric point (p*I*), where they become neutral, and no longer migrate. Here, the proteins focus into discrete zones, and are preconcentrated. Ultimately, a stationary state is achieved when all proteins have migrated into the pH zones that correspond to their p*I*.[11] Mobilization of the proteins into the mass spectrometer is achieved using an electrophoretic approach, hydrodynamic flow, or a combination of these techniques.[11–15,108,122,123] While cIEF/MS has been shown to be useful for the analysis of proteins, the processes of pH gradient formation and analyte focusing are severely perturbed by salt. High salt concentrations lead to excessive currents during the focusing phase of the experiment. This causes ampholyte zone broadening and a less well-defined pH gradient. Recently, we have found that use of a 5–10 min gradient application of voltage facilitates on-line removal of salt.[15] The current profiles observed in these experiments led us to conclude that the relatively slow application of the focusing voltage allows the ejection of highly mobile salt, as the pH gradient is developed and proteins migrate to zones that correspond to their p*I*. This is shown in Figure 1(a) and (b). Here, two protein solutions were analyzed using the same zero EOF, PVA-coated capillary. First, a solution containing lysozyme, cytochrome *c*, myoglobin, carbonic anhydrase, and trypsin inhibitor in water was analyzed using a standard cIEF approach, and the results of this analysis are shown in Figure 1(a). Subsequently, the same proteins were dissolved in water that contained 200 mM sodium chloride. Analysis of the latter solution by a

Figure 1 Capillary isoelectric focusing (cIEF) electropherograms of a five-component protein mixture (a) in the absence of salt and (b) from a solution that was prepared in 200 mM NaCl. Both samples were diluted 1 : 1 with ampholyte solution. Focusing and mobilization solutions were anolyte 50 : 49 : 1 (v/v/v) methanol–water–acetic acid and catholyte 50 : 49 : 1 (v/v/v) methanol–water–ammonia solution. The desalting protocol used for (b) was a linear gradient to 10 kV in 6 min. Protein focusing was at 20 kV for ~20 min. Mobilization was at 20 kV until the experiment was complete and all of the proteins were detected. Protein detection was by ultraviolet (UV) absorption at 280 nm. The CE capillary was 50 μm ID × 37 cm (effective length was 30 cm to the UV detector), and coated in-house with poly(vinyl alcohol) (PVA). (Reprinted with permission from N.J. Clarke, A.J. Tomlinson, G. Schomberg, S. Naylor, *Anal. Chem.*, **69**, 2786–2792 (1997). Copyright 1997, American Chemical Society.)

standard cIEF approach failed. As a voltage of 20 kV was applied to the capillary (over 30 s) to affect analyte focusing, the current rose to ~45 μA and became unstable. It was impossible to obtain satisfactory results from this system without first removing the sodium chloride by means of a slow voltage ramp, and this is demonstrated in Figure 1(b). Clearly, this technique worked well, and was, in our hands, reproducible. As expected, a small shrinkage of the pH gradient was observed. This occurred during the desalting process when cations and anions are mobilized from the capillary and are replaced by counterions of the BGE. While a UV detector was used to acquire the data shown in Figure 1(a) and (b), we have subsequently demonstrated the efficacy of this approach for analysis of physiologically derived protein mixtures by cIEF/MS. It the latter study we demonstrated the detection of glycated hemoglobin chains in diabetic blood and the direct analysis of cerebral spinal fluid by cIEF/MS.[124,125]

Analyte concentrators and mPC devices have also been developed to overcome the relatively poor concentration limits of detection of CE and CE/MS. This technology has been the subject of three extensive reviews.[27,126,127] Briefly, such technology is based upon the insertion of a small bed of adsorptive phase, multiple capillary bundle, immunoaffinity capture support or impregnated membrane at the inlet of the CE capillary (see Figure 2). Principally analytes are adsorbed on a phase to effect their concentration. Injection volumes in excess of 200 μL are routine with this technology, which corresponds to an increase in concentration sensitivity often upwards of 100–1000 times that of a conventional CE injection method. In addition, since analytes are adsorbed on a solid phase or impregnated membrane, on-line sample cleanup can be effected by washing the phase with a suitable solvent.[87,88] For biologically derived peptide and protein samples, this process permits the removal of salt and other hydrophilic contaminants that interfere with the electrophoretic separation of these analytes. This eliminates the need for excessive off-line pretreatment, which improves analyte recovery, which ultimately further enhances concentration sensitivity. Some of these techniques (e.g. mPC) have also been shown to be compatible with contemporary CE stacking and focusing chemistries. Indeed, membrane preconcentration/transient isotachophoresis/capillary electrophoresis/mass spectrometry (mPC/tITP/CE/MS) has been shown to be an optimal technique for the separation and sequencing of low concentrations of peptides.[86–88,96] A major consideration for optimal membrane preconcentration/capillary electrophoresis/mass spectrometry

Figure 2 Schematic diagram of a mPC cartridge. Note the gaps in the cartridge; these are to prevent perturbation of the EOF cause by a high back-pressure in the cartridge if the membrane is compressed. Also, push-fit joints construct the cartridge.

Figure 3 Schematic diagram of the tITP conditions that have been developed for peptide analysis by mPC/CE/MS. Typical conditions are 60 nL of each of the reagents.

(mPC/CE/MS) performance is the use of a sufficient volume of an elution solvent (e.g. 80% methanol or acetonitrile in water) to ensure maximized peptide recovery. However, the use of an excessive volume of elution solvent severely degrades the separation performance of the analysis. Use of a tITP focusing strategy in conjunction with mPC tends to overcome this problem, since analytes are focused into discrete zones as voltage is applied across the capillary.[86–88,96]

The tITP condition that we developed for use in conjunction with mPC/CE/MS is shown schematically in Figure 3. In a systematic study we have shown that mechanistically this stacking/focusing regime is a complex combination of transient cIEF, tITP and analyte stacking, that needs to be fully optimized for each membrane preconcentration/capillary electrophoresis (mPC/CE) capillary used. However, once optimized this system works extremely well. This is shown in Figure 4. Here, a single reversed-phase HPLC fraction that was derived from a biological mixture of rat major histocompatibility complex (MHC) class I peptides were analyzed by mPC/tITP/CE/MS. The power of the technique is demonstrated by the resolution of isobaric peptides (see Figure 4).

We have also used this technique to identify a mouse Kb peptide that promotes T-cell maturation in the thymus. More recently, Hunt's group also demonstrated the value of mPC/tITP/CE/MS for sequencing MHC class I peptides (see Figures 5 and 6). In this example, the mPC/CE capillary was coupled to an ITMS instrument via a novel microspray interface (see later discussions for a review of interface technology).[96] Here, peptide sequencing with attomole sensitivity was demonstrated by the analysis of an immunologically active MHC class I peptide fraction that was isolated from an extract of 10^{10} cells from the human melanoma tumor (DM6) cell line. Full sequence data was achieved

Figure 4 Partial mPC/CE/MS electropherograms of rat RT1^{a}–TAP^{u} MHC class I peptides. The mPC cartridge contained a polymeric styrene–divinylbenzene-impregnated membrane and the CE capillary was uncoated fused silica, 25 μm ID × 70 cm. Injection volume was 50 μL. BGE was 2 mM ammonium acetate in 1% aqueous acetic acid, leading stacking buffer was 1% ammonia solution in water (60 nL), elution solvent was 80% methanol in water (60 nL), trailing stacking buffer was BGE (60 nL). Applied separation voltage was 25 kV. ESI voltage was 2.5 kV referenced to the accelerating voltage (5 kV) of a Finnigan MAT 95Q mass spectrometer. A sheath liquid interface of 60% 2-propanol in 1% aqueous acetic acid was used at 3 μL min^{-1}. Peptide detection was by an electron multiplier, instrument resolution was ~300. Scan range was 300–1300 u at 3 s per decade.

for a known active peptide by membrane preconcentration/transient isotachophoresis/capillary electrophoresis/tandem mass spectrometry (mPC/tITP/CE/MS/MS) (see Figure 6).

While peptide analysis by mPC/tITP/CE/MS can be achieved using an uncoated fused-silica capillary and an acidic BGE, it is our experience that peptides

and proteins are more optimally analyzed using a coated CE capillary.[128] In our studies of MHC class I peptides, tear proteins, and the composition of aqueous humor, we have found a polybrene-coated capillary is most suitable.[128–130] Again, the use of a tITP strategy in conjunction with mPC/CE/MS ensures that a larger volume of an elution solvent can be used with little detriment to the separation performance. Indeed, it has been our experience that unless a relatively large volume of elution solvent is used, proteins are not efficiently recovered from currently available impregnated membranes. In a systematic study, we found that the composition of the elution solvent was critical for elution of proteins from a C_2-impregnated membrane.[129] Increasing acetonitrile concentration from 40 to 80% in water significantly improved protein recovery from the membrane, and overcame a selectivity problem at the lower acetonitrile concentrations. Furthermore, we demonstrated that there was no requirement for the addition of an acid to this elution solvent. Indeed, addition of 0.1% trifluoroacetic acid (TFA) to the 80% acetonitrile elution solvent had only detrimental effects on protein separation.[129] We attributed this result to localized interaction of the TFA, an efficient ion-pair reagent, with the positively charged polybrene-coated capillary. In addition, we found that use of a less efficient ion-pair reagent (such as acetic acid) did not influence protein recovery. We attributed this result to the fact that gaps are deliberately introduced in mPC cartridges as they are prepared. This prevents perturbation of EOF by the cartridge. However, turbulent mixing of injected solvent will also occur. Thus while an elution solvent of 80% acetonitrile in water is injected into the mPC/CE capillary, proteins will be eluted from the membrane by the formation of a solvent gradient. As acetic acid is a constituent of a typical BGE for this application, the front edge of the elution solvent will be modified with this reagent. We postulate that this would tend to be beneficial for the recovery of analytes from the membrane.[129]

Subsequent to the systematic study, we have successfully applied mPC/CE and mPC/CE/MS to the analysis of several physiological fluids, including cerebrospinal fluid (CSF), tears, and aqueous humor [see Figure 7(a) and (b)].[130] In this example we demonstrate the use of mPC/CE/MS to allow a comparison of the composition of ''normal'' aqueous humor (taken from a patient undergoing cataract surgery) and that which was obtained from an individual with PEX syndrome. Several proteins have been tentatively identified from these studies, and we have found few qualitative differences in the composition of the syndrome sample and the control. One lead that we are currently pursuing is the absence of a protein of molecular weight 13 343, and its putative oxidized form (molecular weight 13 361) in the PEX sample, and these studies are on-going. During these studies, we found that protein recoveries were often poor (<25%) and irreproducible when we analyzed standard mixtures of these analytes. In contrast, the recovery of components of physiologically derived protein mixtures was much higher (>90%). We attributed this result to the presence of high salt concentrations in these later solutions that tended to modify the adsorptive properties of the C_2-impregnated membrane.

From our studies it is clear that mPC/CE/MS analysis of protein mixtures is still in its infancy, being limited by the current choice of impregnated membranes. This approach will undoubtedly improve in the future as new impregnated membranes of more appropriate

Figure 7 mPC/CE/MS analysis of human aqueous humor. (a) 1 μL of ''normal'' aqueous humor and (b) the same volume of aqueous humor taken from a patient with pseudoexfoliation (PEX) syndrome. The mPC cartridge contained a C_2-impregnated membrane, and the CE capillary was 50 μm ID by 70 cm polybrene-coated. BGE was 2 mM ammonium acetate in 5% aqueous acetic acid, the elution solvent was 80% acetonitrile in water (60 nL), and the trailing stacking buffer was 0.5% ammonia solution in water (60 nL). The applied separation voltage was 25 kV. ESI voltage was 2.5 kV referenced to the accelerating voltage (5 kV) of a Finnigan MAT 900 mass spectrometer. A sheath liquid interface of 60% 2-propanol in 1% aqueous acetic acid was used at 3 μL min^{-1}. Protein detection was by the PATRIC™ detector, instrument resolution was ~300. Scan range was 300–2500 u at 3 s per decade.

physicochemical properties (e.g. wide-pore polymeric phases such as PLRP-S 4000 Å) become available. In addition, further development of affinity capture analyte concentrators will prove to be very valuable for the isolation and analysis of target proteins.

3.3 Capillary Surface Technology

As mentioned previously, CE was initially thought to be a new approach that would revolutionize the analysis of peptides and proteins.[6] For some applications (e.g. the sequencing of MHC class I peptides) CE has been proved to be extremely valuable. However, capillary surface technology has proved to be a major challenge for the analysis of these important biopolymers. Indeed, manufacture of fused-silica capillaries that exhibit constant surface properties has been the subject of much industrial research by companies that supply this consumable to the users of CE. In our own hands, we have found that while a CE capillary that is prepared from a bulk supply may provide high performance, the next length of fused-silica may not condition at all. In addition, there is no way of predicting in advance which piece of fused-silica will work, and this can be both frustrating and time-consuming. For peptides and proteins, capillary preparation is further complicated by potential analyte–wall interactions. As noted above, the internal surface of a fused-silica capillary is ionized when filled with an aqueous BGE. While the degree of ionization is dependent upon the pH of the BGE, the ionized silanol groups of the CE capillary provide an active anionic surface to which peptides and proteins can adsorb.[98–100] This problem is particularly evident for proteins. These analytes are amphiphilic, such that their structure and chemical environment determines their characteristics (e.g. charge, polarity, and hydrophobicity).

The interactions of proteins at the liquid–solid boundary of fused-silica CE capillaries have been thoroughly investigated.[98–101] Forces that are invoked during these interactions include electrostatic, ion pairing, hydrophobic, and the formation of hydrogen bonds. In CE separations adsorption equilibria between proteins and the capillary wall cause severe zone broadening. Peaks also become asymmetric, which leads to decreased analyte resolution and separation efficiency. Furthermore, a changing capillary surface also affects the magnitude of the EOF, and analyte separations become irreproducible.

To negate analyte–wall interactions, major efforts have been directed toward shielding or inverting the negative charge on the capillary wall. Various capillary coatings have been described [for a review of this subject, see Schomburg[104]]. These include polymers, such as polyacrylamide (PAA), polyethylene glycol (PEG), polyethylenimine (PEI), PVA, aminopropyltrimethoxysilane (APS), and C_8 and C_{18} phases that contain siloxane-bound anchor groups for covalent attachment to the capillary surface. Alternatively, static coatings such as PEI and polybrene have been adsorbed on the capillary surface prior to the analysis of peptides or proteins. Similarly, dynamic coatings such as PVA can be added to the BGE in an attempt to eliminate the interaction of analytes with the capillary wall. There have also been some investigations of the use of polymeric capillaries.[131–133] However, these were difficult to make with a consistent small ID, and did not readily overcome the issue of protein interaction with the capillary wall, since even polymers can take on a charge during electrophoresis.

By design, all capillary coatings change the chemistry of the silica surface. Characteristics of the polymer or chemical coating determine the nature of the capillary surface. For example, hydrophilic neutral coatings (such as PVA, PEG, and PAA) impart no charge to the capillary wall and effectively eliminate EOF.[104] In these capillaries analyte resolution is based solely upon the differences of electrophoretic mobility of each analyte. Other coatings such as PEI, APS, polybrene, or surfactants such as cetyltrimethylammonium bromide reverse the charge on the capillary wall, and EOF flows from the cathode to the anode.[104] CE capillaries coated with such positively charged materials have been shown to be especially advantageous for the analysis of basic proteins. More recently, we have reported that a polybrene-coated capillary is very useful for the analysis of the protein composition of physiologically derived fluids (such as aqueous humor). Indeed, separations in a polybrene-coated capillary were found to be less affected by the salty matrix of this fluid than other tested capillary coatings. In fact, in capillaries that were coated with a neutral polymer, we found that the high salt concentration of these samples prevented the separation of the proteins that were present in physiologically derived fluids. Often only one peak was observed during separations under these conditions.

For CE/MS experiments, the use of a coated capillary further complicates this methodology. If the coating is not sufficiently anchored to the capillary wall, it can bleed into the mass spectrometer. Here it be may ionized, thereby generating a large chemical background or interfering with electrospray processes to impair stability or reduce analyte sensitivity. Hence, in addition to preventing analyte adsorption, the coating has to be stable and remain in the capillary. Most of those described above, with the exception of the dynamic coating strategy, have been successfully used for protein analysis by CE/MS. In general, coatings that invert the charge on the capillary wall have been preferred for the CE/MS analysis of proteins.[109,119,129,130,134–139] This can be attributed to the stability of such coating in acidic BGEs, which is a regime that also promotes the formation of positively charged analytes, thereby enabling the use of positive ion MS conditions.

3.4 Capillary Electrophoresis/Mass Spectrometry Compatible Buffers

As alluded to above, the BGE used in the CE capillary to separate analytes can be detrimental to electrospray MS performance.[105,106] Buffers of relatively high ionic strength are often used for CE separations, since these help to prevent analyte–analyte and analyte–wall interactions. Involatile salts are also a favorite choice for CE separations in conjunction with detection methods other than MS. By contrast, volatile buffers (e.g. ammonium salts) of low concentration, ionic strength, and conductivity are typically used for most CE/MS experiments. This is to ensure stable electrospray conditions and help prevent contamination of the mass spectrometer by salts and ultimately instrument break down. For peptides and proteins, Moseley et al. found that acidic buffers of low ionic strength provided the best CE/MS sensitivity when using a sheath liquid interface.[105] More recently, Wahl and Smith compared the effect of BGE composition on CE/MS using both sheath liquid and sheathless electrospray interfaces.[106] The results of this study were in good agreement with theory, and showed that CE/MS sensitivity was reduced with increasing buffer concentration and ionic strength. In addition, comparison of ammonium acetate–acetic acid and sodium phosphate buffer systems indicated that at a 1 mM concentration the latter buffer provided a seven-fold less signal-to-background ratio than the volatile acetate system. This was attributed to the difference in ionic strength and volatility of the examined BGEs. Other results of these studies demonstrated that the sheathless interface often provided better analyte detectability than a sheath liquid interface for most buffer systems. Likewise, a smaller bore capillary allowed improved tolerance of the buffer system, and this was attributed to the lower BGE flow rate. The BGE flow rate in a 10 μm ID CE capillary is approximately 0.8 nL min^{-1} for a 10 mM ammonium acetate–acetic acid BGE.[106]

In other studies, organic modifiers have been added to the BGE, to aid analyte solubility.[140] The use of organic modifiers also changes the physical properties of the separation solution, which can change the magnitude of the EOF.[141] The organic solvent can alter the thickness of the electrical double-layer at the capillary wall, and/or change the viscosity of the BGE.[140,141] As demonstrated in Figure 8, a nonaqueous BGE can also offer advantages for CE/MS analyses of hydrophobic peptides. Here, an ammonium acetate–formic acid BGE system dissolved in a mixture containing only acetonitrile and methanol (75 : 25 v/v) was used to separate two hydrophobic peptides, namely gramicidin S and bacitracin. Both of these analytes are only sparingly soluble in aqueous solution, and poor analyte sensitivity was demonstrated using a conventional aqueous CE/MS BGE (data not shown). However, a nonaqueous BGE permitted efficient analysis of these analytes by CE/MS, when using a sheath liquid interface (consisting of 5 mM ammonium acetate in 80 : 20 v/v 2-propanol–water). Indeed, we were able to detect a number of minor contaminants in the samples of both peptides by CE/MS using the nonaqueous BGE system (see Figure 8).[140]

Figure 8 CE/MS analysis of a mixture of gramicidin S and bacitracin. CE capillary was 50 μm ID by 70 cm uncoated fused silica. BGE was 20 mM ammonium acetate, 0.5% formic acid in a mixture of 75% acetonitrile in methanol. Applied separation voltage was 25 kV. ESI voltage was 3.45 kV referenced to the accelerating voltage (5 kV) of a Finnigan MAT 900 mass spectrometer. A sheath liquid interface of 5 mM ammonium acetate and 80% 2-propanol in water was used at 2 μL min^{-1}. Peptide detection was by an electron multiplier, MS resolution was 1500 (10% valley definition). Scan range was 300–1500 u at 1 s per decade.

4 CAPILLARY ELECTROPHORESIS/MASS SPECTROMETRY INTERFACES FOR PEPTIDE AND PROTEIN ANALYSIS

4.1 Off-line Coupling of Capillary Electrophoresis with Mass Spectrometry

One of the first approaches for connection of CE to MS was via the collection of fractions from the CE capillary followed by independent analysis by MS. By this approach, probe MS techniques such as plasma desorption[142–144] and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI/TOFMS)[145–151] techniques may be used to measure the molecular weight of isolated analytes. In addition, more recently, nanoelectrospray MS has been used to analyze peptide and protein fractions that were collected following analyte separation by CE.[152] In this area of research, one of the more attractive off-line couplings of CE with MS has been described by Zhang and Caprioli[149] They built a moving target system on which components eluting from the CE capillary were deposited. Specifically, the eluent of the CE capillary was collected onto a cellulose membrane that was fixed on the MALDI/TOFMS instrument target, and preloaded with matrix-assisted laser desorption/ionization (MALDI) matrix (e.g. α-cyano-4-hydroxycinnamic acid). The process of depositing small amounts of aqueous solution on the membrane caused the matrix to partially dissolve, which in turn stimulated cocrystallization of analytes and matrix in preparation for subsequent MALDI/TOFMS analysis of the separated analytes. The target was mounted on the mobile block of a syringe pump to allow a single sample track across the membrane, with a time window of ~3.3 min. Detection limits (DLs) (S/N > 3) were found to be ~50 amol for neurotensin and ~250 amol for cytochrome *c* and apomyoglobin. Such DLs are likely to be attributable to the fact that these analytes were not subjected to further manipulation following their collection from the CE capillary. Clearly, this ingenious method overcame some of the early challenges that were experienced as CE was coupled on-line with MS. However, other methods for the off-line coupling of CE with MS, that advocate manipulation of collected analyte solutions may be less favorable. As mentioned above, manipulation of dilute solutions of peptides and proteins can lead to significant losses. Therefore, in our opinion, many of the reported off-line strategies for coupling CE with MS are less attractive techniques for the analysis of peptides and proteins than on-line CE/MS.

The coupling of CE on-line with MS has been the subject of many reports and several reviews. Therefore, the following is a brief discussion of this area [see elsewhere[5,109,153–158] for more comprehensive review of this subject matter].

4.2 Sheath Liquid Interface

The sheath liquid interface has become one of the most preferred methods for connecting the CE capillary to the mass spectrometer. Briefly, the CE capillary is extended though the ion source, and is surrounded by a coaxially delivered sheath liquid.[7,8] This approach has been used for both electrospray and continuous-flow fast atom bombardment (CFFAB) interfaces.[155] Conceptually the sheath liquid interface is the same for both MS devices with the coaxially delivered solution providing sufficient solvent flow through the interface. The sheath liquid also ensures electrical connectivity across the CE capillary,

and in the ESI interface provides the electrical contact for the ESI voltage.

Some challenges have been reported for both ESI and CFFAB interfaces. For the CFFAB design, the ID of the CE capillary must be small (typically $<13\,\mu m$ ID). This interface is inserted into the high vacuum of the mass spectrometer, and vacuum-induced flow becomes a problem for wider bore capillaries, resulting in a dramatic loss of separation efficiency.[155] The ESI interface does not suffer this problem since ionization occurs at atmospheric pressure, and capillaries as large as $100\,\mu m$ ID have been successfully coupled to this interface. However, as mentioned above, use of such wide-bore capillaries establish further constraints on buffer concentration and ionic strength, which can impair both analyte resolution and CE separation efficiency.[106]

Karger et al. investigated ionic mobility in CE/MS using a sheath liquid interface.[159] Since ions migrate towards both anode and cathode, ionic components of the sheath liquid can migrate into the separation capillary. Both sharp and diffuse ionic boundaries were detected, and resulted in migration delays, inversion of migration order, and often loss of analyte resolution. This effect is shown in Figure 9(a) and (b). Here, while the BGE was the same in the two experiments, replacement of a sheath liquid containing 1% acetic acid in 50% methanol–water by 20 mM TFA in 50% methanol–water had a dramatic effect on the analysis of a mixture of proteins. The time of the separation was compressed and the protein resolution was significantly different. Hence the sheath liquid is a further parameter that requires close attention. In addition to avoiding the possible detrimental effects on analyte separation (described above), careful selection of the sheath liquid can also lead to the use of BGEs that contain involatile buffers. Ions present in the sheath liquid can penetrate the CE capillary to prevent such involatile salts from entering the interface. Furthermore, this process can effectively remove adducts (e.g. phosphates) from proteins prior to entering the mass spectrometer. Similarly, we have noted on occasion that proteins may not be detected at the mass spectrometer (even though they have been seen to migrate passed a UV window that is close to the inlet of the CE capillary) when using a mostly organic sheath liquid interface. In addition to the above explanation, we have postulated that the mostly organic sheath liquid causes the proteins to precipitate as they elute from the CE capillary. As a result, proteins are neither ionized nor detected.

One of the major disadvantages of the sheath liquid interface is that it can introduce a large chemical background into the mass spectrometer. This tends to compromise analyte sensitivity, which is a problem that has been addressed by the use of a sheathless

Figure 9 CE/MS analysis of a model mixture of proteins: 1, cytochrome *c*; 2, lysozyme; 3, aprotinin; 4, myoglobin; 5, RNase A; 6, β-lactoglobulin B; 7 and 8, β-lactoglobulin A and carbonic anhydrase; 9, α-chymotrypsinogen A. CE/MS conditions were BGE 20 mM β-alanine–formic acid at pH 3.4, CE capillary was $75\,\mu m$ ID by 60 cm. Separation voltage was 25 kV. Liquid sheath interface was (a) 1% acetic acid in 50% methanol–water and (b) 20 mM TFA in 50% methanol–water. (Reprinted with permission from F. Foret, T.J. Thompson, P. Vouros, B.L. Karger, *Anal. Chem.*, **66**, 4450–4458 (1994). Copyright 1994, American Chemical Society.)

interface,[106] or low sheath flow design. Kirby et al. advocated this latter approach.[108] Reduction of the annular volume between the sheath liquid needle and the CE capillary allows the use of lower sheath liquid flow rates ($<100\,nL\,min^{-1}$ has been reported). As a result, less chemical noise is detected and the S/Ns of analytes of interest are improved. A particularly useful application of this interface is its use in conjunction with CE capillaries that have negligible or zero EOF.[108] Such capillaries require the makeup flow of the sheath liquid to maintain stable spray conditions.

Most recent reports of the connection of CE with MS have focused upon the use of an ESI interface. This is due primarily to the fact that the outlet of the CE capillary is at atmosphere, hence the MS vacuum does not influence analyte separations. In addition, a major limitation of the CFFAB source is that the ions produced typically exhibit a small number of charges. For proteins, this requires an instrument with an extended mass range. By contrast, the ESI produces multiply charged gaseous ions from solution. Since all mass spectrometers measure mass-to-charge ratio (m/z) values, this effectively extends the mass range of the instrument and permits the analysis of large proteins using relatively inexpensive mass analyzers (such as standard mass range quadrupole instruments).

4.3 Liquid Junction Interface

The liquid junction interface has also been used to couple CE on-line with both ESI and CFFAB interfaces.[155] In this device the CE capillary is placed in a buffer reservoir. Analytes are transported to the mass spectrometer using a transfer line that is positioned in the buffer reservoir in close proximity (~10–25 μm) to the CE capillary. Alignment of these capillaries has been shown to be critical, and Henion et al. have described a modified liquid junction interface in which the CE and transfer capillaries are self-aligning.[156] One of the advantages of the liquid junction interface is its tolerance of involatile BGEs.[5] In addition, this interface was used to successfully couple gel-filled CE capillaries to the mass spectrometer.[160] However, the ease of set-up and use of the sheath liquid interface have ensured that this interface is usually the one of choice, especially by those new to CE/MS.[107]

4.4 Sheathless Interfaces

A sheathless ESI interface has several significant advantages over sheath and liquid junction designs.[109] First, there is a reduced chemical background. Also, since there is no makeup solution that can compete with analyte for the available charge, sensitivity is enhanced. For peptides and proteins, low femtomole sensitivity has been reported. In addition, more recently, peptide sequencing with attomole sensitivity has been reported for a combination of mPC/CE with a sheathless ESI interface, using an ion trap mass spectrometer (see Figure 6).[96]

Sheathless ESI interfaces typically conform to one of six major designs, shown in Figure 10(a–f). The

Figure 10 Schematic diagram of a series of microspray CE/MS interfaces.

simplest sheathless interface (Figure 10a) is usually made by etching and tapering the fused-silica, which is then coated with gold[161] or conducting epoxy.[109] Other designs include the insertion of a wire into the outlet of the CE capillary (Figure 10b)[82] or the use of a thin wire between the CE capillary outlet and a transfer capillary (Figure 10c).[111,128] A low-volume metal union has also been used to connect a transfer line to the CE capillary (Figure 10d).[82] Smith et al. described the use of a dialysis tube to cover a fracture close to the outlet of the capillary (Figure 10e),[162] and more recently, Hunt et al. described a further sheathless CE/MS interface (Figure 10f).[96]

Each of these designs has its merits and challenges, and these have been evaluated (for some of the above-mentioned interfaces) by Herring and Qin.[82] They evaluated the most appropriate CE/MS methodology for the analysis of phosphorylated tryptic peptides of myosin I heavy chain (MIHCK). Again, a method of analyte preconcentration on-line with the CE capillary was preferred to allow efficient sample handling. The findings of Qin and Herring are summarized in Table 1. One of the most common problems encountered during these studies was electrolysis and the generation of hydrogen bubbles at the junction of the CE capillary and the ESI emitter.[82] This invariably stopped the EOF, thereby terminating the experiment. To overcome this significant challenge, Qin and Herring inserted a 10-μm palladium wire into the outlet of the CE capillary (Figure 10b), which also acted as the ESI emitter. In their hands, this interface was reported to be easy to construct. In addition, a very useful property of palladium for this application is that it can absorb >900 times more hydrogen than its own volume. Therefore, unlike some of the other interfaces tested in their study, this simple sheathless CE/MS interface design did not suffer problems associated with hydrogen bubbles halting EOF. However, this interface did tend to induce the oxidation of some peptides.[82] For example, multiple oxidation of bombesin (EQRLGNQWAVGHLM) was demonstrated (see Figure 11). The placement of the palladium wire within the CE capillary also caused turbulence, and some loss of analyte resolution. However, these investigators were able to obtain good MS sensitivity for the two phosphopeptides expected in a tryptic digest of MIHCK, using this interface in conjunction with their adaptation of on-line solid-phase extraction/capillary electrophoresis/mass spectrometry (SPE/CE/MS).[82]

Clearly, miniaturized sheathless CE/MS designs will dominate the future of this technology. It is hoped

Figure 11 CE/microspray mass spectrum of bombesin using a palladium wire interface (Figure 10b). Note the mass difference of 8 u, corresponding to multiple sites of oxidation of this peptide. (Reproduced with permission of Dr Jun Qin and Christopher Herring.)

Table 1 Comparison of four microspray CE/MS interfaces (results are published with permission of Jun Qin and Christopher Herring)

Interface	Figure	Potential advantage	Observation by Qin and Herring	Reported limitations
Tapered coated tip	10(a)	Zero dead volume	Interface is not robust, conductive epoxy is lost within 2 days of operation	Interface needs to be rebuilt following loss of epoxy
			Interface works well for short periods	Oxidation of peptides can occur
Palladium wire	10(b)	Easy to construct Palladium adsorbs hydrogen	Easy to construct No loss of flow due to hydrogen bubbles	Some disruption to analyte resolution due to wire-induced turbulence Some peptides are prone to oxidation
Metal junction	10(d)	Very easy to construct Should be reliable	Electrolysis stopped flow within minutes of electrophoresis	EOF was not fast enough to elute hydrogen bubbles from the interface
Dialysis junction	10(e)	Small dead volume Relatively easy to construct	Tubing was prone to swelling, creating a large dead volume	Capillary alignment was lost owing to the swelling of tubing

that a consensus will be reached by the community as to the most appropriate way to achieve a sensitive and robust design for this approach of interfacing CE with MS.

4.5 Sample Preparation

As mentioned above, extreme caution is required during preparation of dilute solutions of peptides and proteins. These analytes readily adhere to every surface that they contact. Therefore, manipulations need to be minimized. However, biologically relevant peptides and proteins are often most soluble in solutions of high ionic strength. Such solutions are usually not optimal for separation by CE. Typically, these solutions will reduce the effect of stacking mechanisms, or compress the pH gradient in cIEF separations.[15,116] Clearly, the salt concentrations need to be reduced. However, this should not be at the expense of analyte concentration. In this regard, use of an on-line sample preparation (e.g. SPE/CE/MS or mPC/CE/MS) appears to be most appropriate.[27,50–96]

As described above, these techniques enable analyte preconcentration and sample cleanup with minimal intervention by the operator. Improved analyte recovery results. Furthermore, as we have found in our studies, the salt in the sample matrix may aid protein recovery from the solid phase or impregnated membrane.[129,130] Also, traces of salt that remain after such on-line cleanup may improve analyte stacking, provided a positively charged capillary is used for analyte separation.[129,130] For peptides the combination of reversed phase HPLC off-line with mPC/CE/MS has been proven to be a sensitive method of analysis, since subsequent sample preparation involves merely removing the organic solvent from fractions and diluting the residue in a suitable aqueous solvent.[87,88,96] This method could be further improved by on-line coupling of these techniques, as has been demonstrated by Jorgenson's group.[163] However, this tandem technique requires that the mass spectrometer is capable of high sensitivity at fast scan rates, since the CE separation is usually complete in just a few seconds. As such the development of instruments for fast scanning, highly sensitive electrospray ionization/time-of-flight mass spectrometry (ESI/TOFMS) will make this technology more viable.[120]

An area that has currently received only scant attention is that of on-line digestion CE/MS.[164] Such methodology, demonstrated by Kuhr and his group, appears to be a useful way of generating peptide maps of small amounts of biologically relevant proteins.[56,57,164] In conjunction with on-line SPE/CE/MS or mPC/CE/MS, digestion in an open-tubular enzyme capillary or an enzyme-modified solid support would appear to be a powerful methodology for proteomic research. Furthermore, up-front separation by an appropriate chromatographic step (either HPLC or CE) could provide an attractive method for characterizing the protein composition of a biological system, that once optimized would need little operator intervention. Hence analyte losses and sample contamination should be minimized. On-line, automated peptide/protein sequencing using tandem mass spectrometry (MS/MS) could also be achieved by this integrated approach.

5 METHOD DEVELOPMENT

Capillary preparation is the first consideration during the development of a new method. The approach taken is dependent upon the separation mechanism that is considered to be appropriate to yield analyte resolution. The simplest approach is to use a solution of sodium or potassium hydroxide (or methoxide) to etch and clean the silica surface. Following such cleaning, the capillary is usually washed with water and BGE. The capillary is then considered to be ready for analyte separation. However, for peptide analysis it is our experience that the capillary needs to be conditioned before it yields optimal performance. Therefore, in our hands, we usually analyze a standard solution of peptides until reproducible performance is obtained.[165] Typically, 2–5 analyses of the standard peptide solution are sufficient to condition the capillary, but, as noted above, there are some capillaries that do not yield acceptable performance. During our early encounters with CE and CE/MS, we would replace such capillaries and restart the laborious, time-consuming conditioning procedure. As we became more sophisticated users of CE, we found that flushing those capillaries that would not condition (in the conventional manner described above) with a solution of 70% formic acid in 1-propanol would restore CE separation performance.[166] This solution has been reported to remove hydrophobic proteins from HPLC columns, and may be flushing hydrophobic contaminants (that were introduced during manufacture) from the capillary. However, it was also apparent that the silica surface was modified, since subsequent washing of the CE capillary with potassium hydroxide immediately degraded the CE performance. In addition, we proved that this effect was not merely due to the use of a concentrated acid solution, since rinsing the capillary with 1 M hydrochloric acid was not able to restore the separation performance.[166]

It has been shown that in free solution peptide migration follows a linear relationship with $m^{2/3}/z$, where m is the molecular weight of the peptide and z is its

charge or valency [see McCormick[167] for a review of this subject]. Consequently, several computer programs have been developed to correlate the p*I* of a peptide with the charge on the molecule at a given pH. Therefore, if the peptide composition of a mixture is known, the free solution CE conditions that would effect separation can be predicted. From these considerations, the most important parameter that effects the selectivity of the separation is the pH of the BGE. Other parameters such as the ionic strength of the BGE, capillary dimensions, temperature, and electrical field strength influence analyte separation in free solution. However, for peptides, the most direct route to method optimization is to change the pH of the BGE. As mentioned above, BGEs prepared with volatile salts have been reported to be most suitable for all CE/MS studies. Acidic BGEs are usually prepared with mixtures of ammonium acetate and acetic acid solutions, and those at higher pH are typically composed of mixtures of ammonium acetate and ammonia solutions. One issue with these solutions is that they do not exhibit high buffer capacity, and this can lead to irreproducible analyte migration times, as ions are depleted from the BGE. Frequent replenishment of the BGE with fresh solution can overcome this limitation and lead to improved reproducibility of analyte separation and migration.[165] In our studies, we have found for small peptides (molecular weight < 1500) that a solution of 2 mM ammonium acetate in 1% aqueous acetic acid provides a reasonable BGE for analysis by CE/MS.[86–88]

In addition, increasing the acetic acid concentration to 5% tends to enhance peptide separation.[128] Since the pH of the 5% acetic acid solution is very close to that of the 2 mM ammonium acetate in 1% aqueous acetic acid BGE, we attribute the increased peptide resolution to an increased BGE viscosity.[128] More recently, while such ammonium acetate BGEs can be used effectively in uncoated fused-silica capillaries, we have tended to favor the use of the polybrene coating for CE/MS analysis of peptides.[128] As mentioned above, this coating reverses the charge on the capillary wall and tends to prevent peptide adsorption. However, it is our experience that this coating requires conditioning, with the reproducibility of peptide migration times and resolution improving with each analysis. Typically, a polybrene-coated capillary is conditioned within five analyses. This capillary then yields optimal performance for 15–20 separations, after which it has to be completely stripped and recoated (a cycle that can be repeated about 20 times before replacing the capillary).[128] Adding polybrene to the BGE to coat the capillary dynamically during use would keep it functional longer. However, this is not an option for CE/MS studies, since this reagent would enter the mass spectrometer and interfere with ESI processes and method sensitivity. As noted above, the issue of limited CE and CE/MS concentration sensitivity has been addressed by several groups through the development of analyte concentrators and membrane preconcentrators. These have proved to be extremely useful for the analysis of low concentrations of biologically active peptides and enzymatic protein digests. Indeed, we now use mPC/CE/MS exclusively for this application, since it minimizes sample handling, which maximizes analyte recoveries.

The development of conditions for the separation of proteins is considerably more complex than the optimization of CE parameters for peptide resolution. Protein denaturation, aggregation, and precipitation and adsorption on the capillary wall are all factors that can degrade CE performance.[129,130] For most protein separations, a coated capillary is usually essential. Thereby, the complexity of analysis is already increased. In addition, there are a number of separation mechanisms (including free solution, cIEF, cITP, molecular weight sieving, etc.) that can be used to effect the separation of the analytes.[11–24] All of these options and the usual CE parameters need to be considered prior to attempting to separate proteins by CE. We recently evaluated a number of coated capillaries for the analysis of aqueous humor.[168] As noted above, we found that the salt matrix of this physiologically derived fluid interfered with the separation of the proteins that are present in this fluid. In most cases, only a single peak was detected.[168] However, use of a polybrene capillary permitted good resolution of the components of this important physiological fluid. We have also found that a BGE composed of ammonium acetate and acetic acid is very suitable for protein analysis by CE/MS, with increasing acetic acid concentration often improving analyte resolution.[168] Again, we are strong advocates of the use of mPC/CE/MS for this application, since this technique enables both analyte concentration and sample cleanup without excessive sample handling (see Figure 7).[129,130]

6 SEQUENCING PEPTIDES BY CAPILLARY ELECTROPHORESIS/TANDEM MASS SPECTROMETRY

Peptide sequencing by MS/MS, with two mass analyzers coupled via a collision cell, was pioneered by Hunt et al.[169] It is a technique that has provided the sequence of peptides at concentrations that are below the typical DLs of conventional Edman chemistries. The development of the ESI interface, along with on-line condensed-phase chromatography [high-performance liquid chromatography/mass spectrometry (HPLC/MS) and CE/MS] has further extended the use of this approach for peptide sequencing. DLs are often in the sub-picomole range of material. Typical peptide cleavages are shown

Figure 12 Low-energy collision-induced peptide fragmentation pathways in a tandem mass spectrometer.

in Figure 12. Random cleavage of the amide bonds is desired, and often results from low-energy collisions (as are typical in triple-quadrupole, hybrid, or ion trap instruments). It is often possible to read the peptide sequence from both the N- and C-termini from these data. However, there is ambiguity since isobaric amino acids (e.g. leucine and isoleucine) give rise to the generation of identical fragment ions. On occasion, these may be resolved by high-energy collisions, which induce side-chain fragmentation. More recently, the use of protein database searching algorithms has also tended to overcome the problem of identifying the isobaric amino acids.[1] By this approach, peptide sequences are derived by matching the acquired data with peptides that are produced from the known proteins in the database, hence there is often little ambiguity in the amino acid sequence.

In recent years, with the exception of a few isolated cases, high-performance liquid chromatography/tandem mass spectrometry (HPLC/MS/MS) has dominated this area of research.[170] This can be attributed, at least in part, to a better concentration sensitivity of HPLC as compared with CE.[27] Furthermore, chromatographic peak widths may be greater in HPLC separations and more compatible with scan rates of the scanning mass spectrometer. In addition, coupling of the HPLC column to the electrospray interface has been much less challenging to achieve than interfacing CE to the same ionization source. However, CE does afford a second complementary dimension of separation, and we have exploited this to sequence MHC class I peptides.[92,94,171] In a first dimension, these immunologically important peptides are isolated by reversed-phase HPLC. Each fraction is then concentrated to remove the acetonitrile, and analyzed by mPC/CE/MS. Indeed, the development of SPE/CE/MS and mPC/CE/MS has provided technology that has a comparable concentration sensitivity to that of HPLC. However, analyte peak widths of SPE/CE/MS and mPC/CE/MS separations are a challenge to the scanning mass spectrometer (e.g. triple-quadrupole or sector-quadrupole hybrid instrument). As mentioned above, MS sensitivity is reduced at high scan rates. Slowing the rate of data acquisition is often not an option, particularly for CE separations. Often, mass resolution is sacrificed in both mass spectrometers MS1 and MS2 to attempt to regain some of the sensitivity that is lost to the fast scan.[87,88,170] Such a compromise usually leads to a more difficult spectrum interpretation, since isobaric peptides may be introduced simultaneously into the collision cell. Fragments of both are then detected in the resultant spectrum. A further compromise of this approach is that mass accuracy may be sacrificed, with an error in the m/z measurement of fragment ions no better than ± 1 Da. Since this is the mass difference between some amino acids (e.g. I/L and N) ambiguity is introduced into the peptide sequence. However, this situation is often independent of the mode of separation, when sensitivity is pushed to the limits of the scanning mass spectrometer. Reported peptide sequencing sensitivities using scanning MS are comparable to those for HPLC/MS/MS (5 fmol on-column)[170] and mPC/CE/MS/MS (10–50 fmol on-column).[87,88] More recently, ion trap devices (ITMS)[96] and FTMS instruments[172] have been used to acquire peptide sequence data. Indeed, as described above, Hunt et al. have reported 50 amol sensitivity for sequencing MHC class I peptides by mPC/tITP/CE/MS with an ion trap instrument (see Figure 6).[96] Such increase in sensitivity can be attributed to the manner in which these instruments are operated. In these devices ions are trapped and accumulated for a specific length of time. Furthermore, in MS/MS experiments all but the ions of interest are ejected from the trap prior to

peptide fragmentation and subsequent analysis of the generated fragment ions. This approach often leads to a less complex tandem mass spectrum, and if the trap is not overloaded with ions, mass accuracy can be better than is achieved by a scanning instrument. In many areas of research such an increase in sensitivity can reduce the need for growing huge cell colonies, which is both costly and time-consuming. In studies of MHC class I peptide cell colonies, in excess of 10^{10} cells are extracted in contemporary methodologies to yield sufficient peptide for sequencing.[96,170,171] As MS sensitivity is improved this number should fall significantly, and sequencing peptides from a colony of 10^8 cells may become routine in the very near future.

7 FUTURE DIRECTIONS

Developing practices in the area of proteomics will inevitably be more demanding on the sensitivity of analytical methods.[1] Current practices demand that the sensitivity of protein sequencing methods is comparable to that of slab gel silver staining techniques.[110] While these approaches are yielding results, it is likely that many biologically significant proteins will not be detected or characterized. However, at the sensitivity levels that will be required in this area of research, sample manipulations become a major challenge. Both analyte losses and sample contamination by ubiquitous human proteins (such as keratin) become significant issues at picomolar concentrations.[110] Automated preparation and analysis of low-volume, low-concentration samples of high complexity will be required to overcome these issues. Clean-room technology is also likely to become a major requirement of these investigations. Figeys et al. have proposed a solution to these issues.[110] These investigators have suggested the use of coupled microfabricated, integrated analytical modules with MS for this application, and they have proposed microfabricated device/mass spectrometry (MFD/MS) as the acronym for this technology.[110] While research on these devices is in its infancy, such a miniaturized approach coupled with a sensitive mass spectrometer could provide the DLs required in the next generation of proteomic studies. Furthermore, with careful design of the array, on-chip protein isolation, digestion, and analysis could be accommodated in this nanoenvironment.[110] However, the use of nanotechnologies will provide new challenges. First, creative coupling of the macro world of biochemistry to the nanoanalytical environment will be required. In this regard, the lessons learned from the development of mPC/CE/MS and SPE/CE/MS technologies should aid these studies, particularly in the area of reducing potentially long sample injection times, caused by slow liquid flow rates in these nanodevices. The sensitivity of protein sequencing will also require further creative input. In this area, interfacing the microfabricated array to the mass spectrometer will need particular attention.

So far, since MFD/MS research is in its infancy, there have been few reports in the scientific literature.[110,114,115,173] Most devices are prepared using technology that was first described in the computer microchip industry. Typically, reservoirs and microchannels are etched into glass, which is bonded to a second piece of glass, and electrodes are inserted to complete the device. There have also been limited reports of the use of polymers to prepare for this application, and this is an area that may require much more attention. It is known from conventional CE that proteins adsorb to glass capillaries, leading to the development of a large number of capillary coatings to prevent protein adsorption to the capillary wall (see earlier discussions).[104] It is envisaged that similar coatings will need to be applied to a microfabricated device (MFD) to prevent protein adsorption on these devices, and improve separation or manipulation of these important analytes in the nanoenvironment.

Currently, there is no consensus in the literature as to the most appropriate method for interfacing an MFD with a mass spectrometer. It is agreed that the micro- or nanoelectrospray interface is the most efficient ionization source for this application.[110,114,115,173] In one of the approaches described, an array of nine channels was continued to the edge of the device, which served as the ESI/mass spectrometer interface.[173] Analytes were mobilized by the application of pressure to the appropriate reservoir and ionized directly from the edge of the unit. The different channels were moved sequentially in front of the inlet orifice of the mass spectrometer to permit the characterization of individual analytes. Ramsey and Ramsey have described a similar approach, and demonstrated an MFD/MS separation with their device.[114] In contrast, Figeys et al. preferred to use a transfer capillary and a liquid junction microspray (see Figure 10c) to interface an MFD to the mass spectrometer.[110] Enhanced MS sensitivity was given as the reason for their preference for this interface. However, it does significantly extend analysis times. This technique may be most suitable for enhancing separations, by a combined microfabricated device/capillary electrophoresis/mass spectrometry (MFD/CE/MS) approach. More recently, Foret and Karger described the use of ionspray directly from the edge of the MFD.[174] This device includes the ability to apply a nebulizing gas to aid the electrospray processes. However, the use of the nebulizing gas induces hydrodynamic flow within the device, hence a makeup solvent is

required. The use of a makeup solvent inevitably dilutes the separated analytes prior to their transport into the mass spectrometer, and may reduce the ultimate sensitivity of this approach. However, careful selection of this solvent may aid ionization efficiency and thus tend to improve method sensitivity.[174]

A further technology that is expected to improve MS sensitivity is the development of the highly sensitive ESI/TOFMS,[120] and electrospray ionization quadrupole time-of-flight mass spectrometry (ESI/QTOFMS) and a quadrupole ion trap coupled with a reflecting TOF instrument.[175,176] The development of such instruments is well under way. In addition to high sensitivity, these instruments have a short duty cycle, which allows very fast data acquisition, with no loss of sensitivity. These instruments also provide a constant medium resolution (>5000 full width at half-maximum definition) and good mass accuracy. The use of isotopic labeling (as is achieved when enzymatic protein digests are carried out in ^{18}O-labeled water) can aid peptide identification with MS/MS data since only Y ions will contain this label. The mass resolution of the TOF instruments allows ^{18}O-enriched ions to be readily identified in MS/MS spectra, to facilitate peptide sequence identification.[177]

In summary, it is clear that there will need to be a significant pursuit of more sensitivity for CE/MS. In this regard, MFD/MS may, with further development and possible coupling to a highly sensitive mass spectrometer (such as ESI/TOFMS), provide the technology that is needed for future generations of proteomic research. However, lessons learnt in the macro world of CE/MS will need to be heeded as new MFD and MS interfacing techniques are developed. In particular, input by materials scientists may provide improved surfaces to prevent interaction and loss of peptides and proteins within the channels of MFDs. Assuming that these challenges will be overcome, technology for the isolation, manipulation, digestion, and sequencing of extremely low levels of biologically active proteins will become a reality within the next few years.

ACKNOWLEDGMENTS

The authors thank Mrs Diana Ayerhart for her help in preparing this article. They are also grateful to Christopher Herring and Dr Jun Qin (Laboratory of Biophysical Chemistry, National Heart, Lung, and Blood Institute) for sharing the results of their studies of microspray CE/MS interfaces and Professor Hunt (University of Virginia) and Professor Karger (Barnet Institute Northeastern University) for graciously sharing their work. The support of funding by Mayo Foundation, Finnigan MAT, Beckman Instruments, AHAF, and NIH is gratefully acknowledged.

The available methods for the separation of membrane proteins and lipoproteins are sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS/PAGE), followed by immunoblotting, isoelectric focusing (IEF), capillary electrophoresis (CE) and high-performance liquid chromatography (HPLC). In this article it is shown that HPLC techniques, given their wide versatility, relative ease of use, and high resolution, may be considered the most valuable tool for the characterization of virtually any hydrophobic protein. Moreover, HPLC is not a destructive technique and therefore proteins, once separated, are available for further analytical investigations. Application examples are described and comparisons with other methods are discussed.

1 INTRODUCTION

Owing to their lipophilic character, the solubilization and separation of membrane proteins and lipoproteins normally require the use of detergents. Consequently, classical protein purification strategies, designed for water-soluble proteins, are of limited value and the number of reports dealing with the separation and characterization of such proteins is limited. Moreover, their hydrophobic nature induces self-association into noncovalent multimers, and therefore all separative methods require a prior procedure such as tedious sequential gradient ultracentrifugation for sample preparation, with the risk of affecting the results. Although the available methods for the final separation of these hydrophobic proteins are numerous, theirs high hydrophobicity and the presence of detergent makes most of these available methods expensive and technically demanding. The traditional approaches by SDS/PAGE are not only cumbersome but also rather ineffective for evaluating differences in small molecular masses and the run times required are very long, typically more than 20–30 h. CE is emerging as a powerful separation technique for lipoproteins but the number of reports on membrane proteins is still limited. It is not surprising that HPLC techniques, given their wide versatility, relative ease of use, and high resolution, may be considered the most valuable tool for the characterization of virtually any hydrophobic protein. Moreover, HPLC is not a destructive technique and therefore proteins, once separated, are available for other analytical investigations, such as by SDS/PAGE. In any case, before loading a sample on any HPLC system, a preseparation of membrane proteins or lipoproteins, according to their hydrophobic characteristics, must be achieved by selective extractions. The pretreatment of these proteins facilitates subsequent separation and provides a first guideline for the choice of detergent. It is a general rule, in fact, that when choosing the detergent for the running buffers, one should use the one with which the protein was solubilized, if possible. It is also advisable to use less denaturing detergents and nonionic detergents for solubilization and likewise as an additive to the running buffers, in order to retain the biological activity of proteins. The presence of detergent in all steps preserves the subsequent tendency toward association and aggregation and the possibility of nonspecific interactions with the support used for chromatographic separation.

Although lipoproteins and membrane proteins show common features, specific protocols for the separation of each group of proteins have recently been proposed, and therefore they will be presented separately.

2 CHROMATOGRAPHY OF MEMBRANE PROTEINS

Methods for the separation and characterization of membrane proteins differ depending on the type of interaction

of the protein with the membrane: proteins embedded in a lipid bilayer or associated with membrane structures. In the latter case, usually ionic interactions or hydrogen bonds are involved in the anchorage, and therefore the protein may be removed by gentle solubilization with buffered salt solution and then analyzed. Dilute sodium hydroxide and sodium hydrogencarbonate (between pH 10 and 12), concentrated salt solutions, and complex-forming substances such as ethylenediaminetetraacetic acid (EDTA) and ethylene glycol bis(β-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA) are used satisfactorily for their solubilization. In the case of embedded proteins, they must first be extracted from the membrane structures and then isolated. Repeated freezing and thawing can be applied to dissolve the structures mechanically, thereby allowing most membrane-associated proteins to be removed. However, solubilization of the membrane is the most suitable approach. Chaotropic reagents such as urea and guanidine hydrochloride are now used less frequently, while solubilization using detergents is still in principle more practical. It is also advisable to use less denaturing detergents such as 3-[(3-cholamidopropyl)dimethylammonio]-l-propanesulfonate (CHAPS), or nonionic detergents such as n-octyl β-D-glucopyranoside (OD) or *n*-dodecyl β-D-maltoside (β-DM) for solubilization.

Through the use of various reagents in different steps, the membrane proteins can be prepared according to their respective solubility and hydrophobic characteristics. The effort necessary for solubilization of the proteins increases with growing complexity of the membrane structure. In section 4.2.3 is reported a complete solubilization scheme for the thylakoid membrane of chloroplasts which contains the photosynthetic apparatus consisting of a large number of proteins, namely 40 different proteins assembled into two main complexes: photosystem I (PSI) and photosystem II (PSII). It will be shown that by selective extraction, a preseparation of membrane proteins according to their hydrophobic characteristics is achieved. This in turn allows further separation by use of different, mainly chromatographic and electrophoretic, methods.

Once the membrane proteins have been pretreated, several chromatographic methods may be used.

2.1 Methods for Protein Separation and Characterization

With regard to the membrane protein separation, strategies having general validity are reversed-phase high-performance liquid chromatography (RPHPLC), affinity chromatography, size-exclusion high-performance liquid chromatography (SEHPLC) or ion-exchange HPLC and high-performance membrane chromatography. Usually membrane proteins are organized as multimeric units, therefore no single technique is likely to be sufficient for the complete characterization of different proteins. It is important, therefore, to select a battery of complementary techniques that will ensure that the necessary separation is obtained. Specific considerations for selection of an appropriate battery of techniques are described in section 4.

Conventional gel permeation and ion-exchange chromatography on soft gel supports, although time-consuming, are used for the preparation of large quantities (10–50 mg) of pure proteins, while the preparation of smaller quantities is usually performed at low pressure [fast protein liquid chromatography (FPLC)]. HPLC, usually carried out at high pressure (300–400 psi), has been an essential tool for the quantitative and qualitative analysis of proteins. Its success increased when rigid supports, which are able to withstand high pressures and show chemical stability within the working range of biological separations, were introduced. The separation time decreased dramatically.

The first consideration in defining an HPLC method development strategy is to establish if we need proteins with the biological properties preserved or we simply need their characterization. Proteins vary widely in their physicochemical properties and these properties can have a great impact on the conditions necessary for HPLC analysis. Solution stability can differ widely from one protein to another, and for a given protein the solution stability can be highly dependent on pH, temperature, presence of denaturants or detergents, and other factors. Such factors must be explored as part of the separation development process in order to select appropriate conditions and an appropriate detergent under which artifactual denaturation is minimized. Other physicochemical properties to be considered include the presence or absence of free thiol groups or bound metals and the effect of the organic solvent used in RPHPLC on the secondary or tertiary structure. Finally, the presence of detergent must be taken into account along with the possibility of nonspecific interactions with the support used for chromatographic separation. Furthermore, membrane proteins readily self-associate into noncovalent multimers. Hence in some instances one may wish to determine only covalent related substances and it is therefore appropriate to conduct the HPLC separation using conditions that dissociate the noncovalent multimers, whereas in other instances measurement of the extent of self-association may be an objective of the separation.

2.1.1 Reversed-phase High-performance Liquid Chromatography

RPHPLC offers the best resolution of all chromatographic methods, although up to now it has been rarely

used for the separation of membrane proteins. This is because under the separation conditions usually required in RPHPLC [elution with acetonitrile or 2-propanol gradient, in the presence of 0.1% (v/v) trifluoroacetic acid (TFA)], the membrane proteins can be recovered only partly and sometimes not at all. The advent of supports having reduced hydrophobicity, such as a C-4 column, has allowed the use of milder elution conditions with a consequent higher recovery of proteins (see section 4). Clearly, the application of organic solvents and acids causes the loss of the protein biological activity. Thus RPHPLC is a powerful method for the isolation of membrane proteins, whose primary structure is to be investigated subsequently or whose identification is the main aim.

2.1.2 High-performance Affinity Chromatography

Analytical affinity provides a powerful means to purify proteins and other biomolecules with a basic two-step retention–chaotropic elution procedure with minimal nonspecific interactions and their subsequent elution in a highly purified state and in the native state. Successes of affinity chromatography for preparative purposes arose when researchers improved several key features of immobilized ligand interactions with eluting macromolecules, namely accessibility of immobilized ligand, selectivity of ligand interaction with soluble macromolecule, and reversibility of macromolecule binding, which allows their elution without denaturation. In this regard, important parameters for a successful affinity sorbent for bioseparations include mechanical, chemical and biological stability, and also the potential for nonspecific binding. Rigid matrices such as polymeric supports, silica and controlled-pore glass may suffer from nonspecific binding and low recovery. Cross-linked beaded agarose or cellulose offers a good compromise between mechanical stability and nonspecific binding. These matrices also have good chemical stability within the working range of biological separations and the product recovery is excellent. The interested reader is referred to other literature for a discussion of core chromatographic matrices themselves.[1]

Once a matrix has been selected, the ligand is immobilized via a stable covalent bond to avoid progressive leaching and consequent capacity loss. The most common procedure to activate agarose is cyanogen bromide (CNBr), which results in the coupling of an amine group of the ligand or spacer through an isourea bond. Matrices prepared by this procedure can suffer from the serious drawback of high ligand leaching, while more stable linkages are produced by organic sulfonyl chlorides or epihalohydrins.[2]

Lectin affinity chromatography is largely used for lipoproteins, while two steps with protein-specific ligands, namely immunoaffinity (IA) and transition-state ligands, are commonly used for the separation of receptors and enzyme proteins, respectively.[3]

2.1.3 Size-exclusion High-performance Liquid Chromatography

The separation of membrane proteins may be achieved satisfactorily under nondenaturing conditions by SEHPLC. In this case, the size of the molecules or multimeric complexes is the basis of separation, although differences of 5–10 kDa in molecular weight are not sufficient for a significant separation. Since nonspecific interactions between the sample and support, and among different sample components, must be suppressed, sometimes the addition of denaturing agents, such as chaotropic reagents or sodium dodecyl sulfate (SDS), is required. Obviously, under these denaturing conditions, the resolution and yield are optimized in SEHPLC, along with good reproducibility of the results, but proteins may be denatured.

2.1.4 Ion-exchange High-performance Liquid Chromatography

Ion-exchange HPLC is based on the different ionic interactions between proteins and anionic or cationic charges of the support. Unfortunately, in this type of chromatography, protein interaction with the support is usually strong and the conditions used for elution are often denaturing. The advent of supports based on agarose, which owing to its hydrophilic characteristic has a lower level of nonspecific interactions with the sample, has renewed the use of ion-exchange HPLC for protein separations. However, in the particular case of membrane proteins, although the degree of resolution of ion-exchange HPLC is surpassed only by RPHPLC, interaction with the support is still too strong and other methods must be chosen, or detergents must be added to the separation buffers.

2.1.5 Hydrophobic Interaction High-performance Liquid Chromatography

Hydrophobic interaction HPLC can also be used for the isolation of membrane proteins, even if they are so strong that the sample can no longer be recovered from the column, even with the use of detergents or, in extreme cases, organic solvents.

2.1.6 High-performance Membrane Chromatography

Red cells, biomembrane vesicles, proteoliposomes, and liposomes noncovalently immobilized in gel particles or beads have been used as stationary phases

for biomembrane affinity analyses and ion-exchange chromatographic separations. Lipid monolayers coupled to silica beads have been utilized for membrane protein purification in detergent solution. Proteins are adsorbed on the liposome surfaces and subsequently separated by salt gradient elution on charged liposomes formed and entrapped in gel beads upon detergent depletion by dialysis.[4] Hence both protein size and charge affect the separation and the elution time. These techniques, in the particular case of membrane proteins, have considerable potential because of their high resolution, short running times, and low nonspecific interactions. For more details the reader is referred to a review.[5]

2.2 Separation Depending on the Membrane Protein Category

From a didactic point of view, proteins embedded in membranes may be divided on the basis of their biological role into receptors, glycosylated proteins, channel or carrier proteins, and structural proteins or those without a particular function.

The first consideration in defining the development strategy of an HPLC method is to establish whether the main interest is to isolate the protein functionally active or its characterization. In the former case nondenaturanting conditions must be used, whereas in the latter case any type of detergent or organic eluent may be used for the optimum separation.

2.2.1 Cellular Receptors

In the case of receptorial proteins, they rarely exist in aggregated form and they are specific for recognizing a particular ligand. Thus nondenaturating size-exclusion chromatography (SEC) may not be used, and affinity chromatography is more indicated, because immobilized ligands proteins can be bound specifically and eluted selectively. The natural ligand might be an ideal choice for binding selectivity but may suffer from a high intrinsic binding affinity, which could lead to inactivation of the receptor or ligand due to the harsh conditions needed for release from the affinity support. Lectin affinity chromatography is largely used for glycoproteins and IA chromatography is the most widely used method for receptors.

A more practical ligand may be a monoclonal antibody (MAb) to the receptor, which can be preselected for modest affinity and appropriate binding kinetics (on and off rates). In general, to prepare an IA sorbent, MAb is preferred over polyclonal antibody, since the MAb can be obtained once a hybridoma clone has been isolated reproducibly, and second because the appropriate MAb can be selected with the desired binding properties to optimize biomolecular adsorption and elution. The desired elution conditions can be incorporated into the screening procedure to identify the most advantageous MAb. Since the binding constant varies from clone to clone, selection of a clone producing a MAb with a desirable binding constant is necessary. An antibody that gives a good response in either Western blot or enzyme-linked immunosorbent assay (ELISA) is not necessarily the best ligand for the IA sorbent. An example of this procedure is described in section 4.2.2. Interaction analysis using such current tools as optical biosensors can be used to screen MAbs for those with a good balance of sufficiently high affinity and finite off rate (see section 5). Many receptors have been separated by IA.[6] A milestone in this field is the separation of transferrin receptor from plasma membranes of various mammalian cells.[7] It is known that this protein binds with high affinity to immobilized diferric transferrin, whereas its affinity for apotransferrin is low. Consequently, the complex of transferrin and transferrin receptor can be dissociated by chelation of ferric ions after the addition of chelating reagents. In this way transferrin receptor can be eluted from the column under mild conditions.

2.2.2 Carriers or Channel Proteins Translocating Ions

Membrane proteins with the function of carriers or containing channels translocating ions across membranes may be separated and identified by the use of the perfusion planar lipid membrane (BLM) technique coupled with an HPLC system. This technique has been demonstrated to be efficient for the fast identification, isolation and characterization of transport proteins (porins) in the outer membrane of bacteria and other organisms,[8] but it seems to be of general validity.[9] The method is based on solubilization of the membrane, separation of solubilized membrane proteins into fractions (100–150) eluted from an HPLC column followed by immediate screening on the BLM for channel-forming activity, allowing precise localization of the porin-containing protein peak. The principle of the BLM method is simple. A planar lipid membrane interposed between two electrodes is predictably dull, showing little permeability to ions, no voltage dependence, and no interesting transport behavior. However, the introduction of a channel-forming protein, previously separated by HPLC, that is spontaneously incorporated into the bilayer dramatically alters the situation, allowing chemical substances to cross the lipid bilayer and giving rise to an ionic current. Furthermore, the opening and closing of this single ionic channel can be easily detected and modification of the channel properties by voltage, pH, ionic composition, blockers, mutation and chemical reagents can also be quantified. Although the BLM is an in vitro system, its validity has been demonstrated repeatedly through the more recent technique

of patch clamping, giving confidence that what is measured using a BLM corresponds qualitatively and often quantitatively to what is observed in whole cells. BLMs have been intensively used in the identification and reconstruction of channel-forming proteins,[10] to determine the deposition of amyloid proteins observed in Alzheimer's disease pathology,[11] and in the study of membrane proteins of other disease-related bacteria, whose porins or pathogenic toxins might be labile.[9,10]

2.2.3 Glycoproteins

Determination of the carbohydrate composition, type, and branching pattern is an important step in understanding the biological function of glycoproteins and in the development of a recombinant DNA-derived glycoprotein as a pharmaceutical. Unfortunately, glycoproteins exist in a variety of biologically active forms, owing to the nature of the diversity of monosaccharides and the variety of possible linkages. It may be estimated that the linkage possibilities of a hexasaccharide yield a possible 4.76×10^9 structures.[12]

The complexity of carbohydrate structures mandates that a variety of analytical methods be used for the study of these forms.

Lectin affinity chromatography is used to separate membrane glycoproteins, but a promising new procedure is described in section 4 that uses HPLC in conjunction with electrospray ionization mass spectrometry (ESIMS) as a tool to identify the sites of glycosylation and the general nature of the glycosylation. ESIMS can detect whether an oligosaccharide is O- or N-linked and can also differentiate between complex, high-mannose, and hybrid forms.

2.2.4 Others

When the membrane proteins that are to be analyzed do not play any functional role and their identification and characterization are the main aim, RPHPLC offers the best resolution of all chromatographic methods, especially when coupled on-line with a mass spectrometer. In sections 4 and 5 some aspects of this application will be presented and discussed.

3 CHROMATOGRAPHY OF LIPOPROTEINS

The term lipoprotein refers to particles which are heterogeneous with respect to size, hydrated density, and composition. The main function of the lipoprotein system is to transport lipids to surrounding tissues. All are made up of cholesterol, cholesterol esters, triglycerides, phospholipids, and apoproteins in varying proportions. Lipoproteins have a globular structure containing hydrophobic lipids such as triglycerides and cholesterol esters within the interior core, and a periphery containing more polar lipids, phospholipids, cholesterol, and proteins.

Owing to their strong heterogeneity, classification of lipoproteins remains undefined. Hydrated density is the more common form of lipoprotein classification. Thus lipoproteins are separated into very low-density lipoprotein (VLDL), low-density lipoprotein (LDL) and high-density lipoprotein (HDL) fractions. In this case, lipoproteins are viewed as particles which are heterogeneous with respect to their physical properties but homogeneous with respect to apoliprotein composition. The HDL, LDL and VLDL groups show different functions, which results in their having different properties with respect to atherosclerosis, and therefore it is very important to have methods available for their separation.[13] On the other hand, due to the growing evidence that apolipoproteins are better markers of coronary heart disease (CHD) than are serum cholesterol levels,[14] and that the apoliprotein distribution is important in diagnosing lipoprotein abnormalities, the separation and characterization of lipoproteins with respect to protein composition is of increasing interest. In Table 1 are summarized the physical and chemical properties of the main lipoprotein classes and their subfractions and also the different types of apoproteins and their isomers.

3.1 Methods for Lipoprotein Separation

As an alternative to ultracentrifuge separation, gel permeation separation does not require expensive ultracentrifugation instrumentation and has the advantage of being relatively mild and nondestructive in the separation

Table 1 Physical and chemical characteristics of lipoproteins: subfraction classes and apolipoproteins

Lipoprotein class	Diameter (nm)	Subfractions	Major apolipoprotein	Apolipoprotein isomers
VLDL	30–70		ApoC, apoB, apoE	ApoC-I, C-II and C-$III_{(0,1,2)}$ ApoE-1, E-2, E-3, E-4, E-5 ApoD
LDL	17–26	5	ApoB	Apo-B_{100} Apo-B_{48}
HDL	7–9	5	ApoA-I, apoA-II, apoE	ApoA-$I_{1,2,3,4}$ ApoA-II and A-IV

of lipoprotein particles. Gel permeation and affinity chromatography are used satisfactorily for preparative purposes and to separate lipoproteins according to size and apolipoprotein content, respectively. However, these chromatographic methods have not gained wide acceptance as routine techniques, requiring long analysis times and excessive dilution of samples during separation. In this respect, the development of rigid supports for gel permeation has led to large improvements in speed and resolution. Gel permeation chromatography (GPC) of whole plasma is now used primarily for analytical rather than preparative separation of plasma lipoproteins.

The advent of RPHPLC resulted in renewed interest in the chromatographic separation of lipoproteins, offering the best performance in terms of speed and resolution of structural variants. In particular, the use of rigid supports, which are able to withstand high pressures, decreased the separation time dramatically to 1 h compared with 20 h by the conventional gel permeation method. Furthermore, the separation may be easily automated, allowing unattended analysis of multiple samples. Automation also allows on-line monitoring of cholesterol in the separated LDL and HDL fractions (see later).

Two new emergent chromatographic techniques for lipoprotein separations are hydroxyapatite and countercurrent chromatography (CCC).[15] Their combined use allows a better separation and analysis of HDLs, LDLs and VLDLs from human serum without prior ultracentrifugation (see section 5).

3.1.1 Separation by Particle Size and Subfractions

Gel permeation is normally used to separate lipoproteins on the basis of differences in particle size. It was initially performed on cross-linked dextran supports, which, owing to their relatively small pore size, yielded poor separations, whereas by agarose gel, which has a larger pore size, has been found to yield better separations.[16] Usually the eluting lipoproteins are derivatized postcolumn with an enzymatic cholesterol reagent, and therefore the mixture is passed through a reaction capillary and detected at 500 nm. Complete separation is usually achieved in less than 80 min.[17]

Separation of the main classes of lipoproteins into their subfractions is of growing interest since each subfraction has a different specific physiological function. By GPC, HDL particles may be divided into five subfractions,[18] whereas by heparin affinity chromatography, HDL may be subfractionated according to the apoE content.[19,20] By ion-exchange chromatography, five different fractions of oxidatively modified LDL were identified.[21] The human serum HDL fraction may be divided into five or six subclasses by using hydroxyapatite chromatography.[15]

3.1.2 Separation of Apolipoprotein and Isomers

Affinity chromatography, which employs specific and reversible interactions between lipoprotein and bound ligands, is capable of separating lipoproteins on the basis of their apolipoprotein content. Affinity chromatography of lipoproteins can be performed using group-specific or biospecific ligands. Group-specific ligands include concanavalin A, which binds to apoB-containing lipoproteins,[22] and heparin, which interacts specifically with apoB and apoE,[23] while antibodies to specific apolipoproteins serve as biospecific ligands in IA chromatography. This technique provides the highest specificity for the separation and isolation of lipoproteins on the basis of their apolipoprotein content, while group-specific ligands are more economically convenient but the separation is less accurate.

In addition to affinity chromatography, the high-performance gel permeation, ion-exchange or reversed-phase mode may be used to separate apolipoproteins into their isomers. Unfortunally, in these HPLC systems only small amounts of sample (<5 mg) can be applied to the column. However, the speed (<60 min) and ease of operation make these techniques ideal for the analytical separation and characterization of apolipoproteins. GPC is often used as a preparative technique for isolating apolipoproteins derived from HDL or VLDL, while separation of isoforms can be achieved by either ion-exchange or RPHPLC. Apolipoproteins from HDL and VLDL can be separated in less than 60 min on high-performance TSK gel permeation columns.[24] Separations of apolipoproteins by ion-exchange chromatography are based on differences in charge. Therefore, this mode of chromatography can separate apolipoproteins with different isoelectric points.[21] In contrast, differences in hydrophobicity are the basis of separation by RPHPLC. The reversed-phase columns usually have a lower sample capacity (<100 mg) than those used in gel permeation HPLC. Moreover, the column lifetime is relatively short, owing to the instability of silica-based stationary phases at pH extremes. However, there is growing interest in the use of RPHPLC as a rapid and highly efficient technique for monitoring heterogenicity in apolipoprotein structure.[25]

4 APPLICATION EXAMPLES

As mentioned above, the separation of membrane proteins and lipoproteins will be presented separately owing to the specificity of the methods set up for the two main protein categories. However, in both cases HPLC is the most convenient method used, and therefore a few considerations specifically relevant to the instrumentation required are presented.

4.1 Experimental Considerations

In the case of proteins, more than for small organic compounds, HPLC requires extremely precise control of the solvent composition, because the RPHPLC elution time is much more dependent on organic solvent composition. Single-pump, low-pressure mixing HPLC gradient systems are widely used for protein analysis. However, when using solvents that are difficult to mix (e.g. 1-propanol), dual-pump, high-pressure mixing is advantageous because the two solvent streams are delivered continuously rather than delivered in a segmented fashion. Moreover, with single-pump operation the continuous sparging of solvents with helium, for degassing purposes, results in changes to the organic solvent composition. This problem may be minimized by presaturation of the helium with organic vapor by passing the sparge gas through a solvent reservoir containing the mobile phase.

With respect to detection, generally either 280- or 214-nm wavelengths are employed for protein analysis. Detection at 214 nm is more sensitive and more generally applicable because absorption at this wavelength is due to the peptide backbone. However, some HPLC mobile-phase constituents may interfere at this wavelength (e.g. acetate salts). Detection at 280 nm is somewhat less sensitive, but can be used to detect most proteins (absorption at 280 nm is primarily due to the aromatic amino acid side chains of tryptophan, phenylalanine and tyrosine). In some cases, dual-wavelength or diode-array detectors are recommended in order to provide more detailed spectral information for each peak observed.

In general, the sample solution should be similar in composition (e.g. pH) to the HPLC mobile phase so as to minimize the effect of the sample injection on the separation efficiency. One exception to this rule is RPHPLC, where the organic solvent composition of the sample should be less than that of the initial mobile phase in order to focus the injected proteins at the head of the column. Clearly, the protein must have adequate stability in the selected solvent and in many cases stability must be enhanced by use of a refrigerated autoinjector. When conducting size-exclusion HPLC for determining noncovalent multimers, one must avoid the use of denaturants (e.g. organic solvents) or extreme pH conditions that might disturb the equilibrium between monomer and multimer forms.

Clearly the column is the heart of the HPLC separation system. Unfortunately, this is the one component over which the analyst has the least direct control. Consequently, it is important to work closely with the column manufacturer to obtain several independent column manufacturing batches, and to investigate whether a particular method performs consistently on a number of such batches. Whenever possible, an HPLC method to be used on a routine basis should be validated using two alternative sources (brands) of columns, in order to minimize the impact of column manufacture problems.

The advent of new reversed phases such as C-4 allowed excellent separations of hydrophobic proteins with a high protein recovery (see later). The use of microbore HPLC and packed capillary HPLC for characterizing biosynthetic proteins is becoming more widespread. However, such techniques have not been widely adopted for routine use or method development within the laboratory owing to limitations on hardware and the relatively large amounts of assay material available. As hardware advances occur, this situation may change because the advantage of lower solvent consumption is clearly attractive. Furthermore, such techniques are more compatible with high-performance liquid chromatography/mass spectrometry (HPLC/MS) systems, which are now widely available and offer profound advantages for method development (see section 5).

4.2 Membrane Proteins

Here three examples are presented.

4.2.1 Cellular Receptor

CD4 is an integral membrane glycoprotein of T cells that acts as the cellular receptor for human immunodeficiency virus (HIV). Many protocols have been set up to recognize and separate CD4. All are based on IA, using monoclonal antibodies and autoantibody[26] directed against conformational epitopes of CD4.

4.2.1.1 Selecting a Monoclonal Antibody Soluble CD4 (sCD4) has been considered as a possible therapeutic agent for acquired immune deficiency syndrome (AIDS) by acting as a molecular decoy, i.e. by binding to the gpl20 coat protein of HIV and thereby preventing cellular binding of HIV. Consequently, there is a growing interest in searching CD4 variants from either mammalian cell culture or microbial extracts, showing improved pharmacokinetic properties. A rapid generic purification scheme for sCD4 constructs has been developed using IA separation. To prepare a robust IA sorbent for the purification of sCD4, a number of sCD4 mutants and a series of MAbs were examined.[3] Five different commercial anti-CD4 monoclonal antibodies were immobilized through protein amino groups on to a Sepharose matrix containing an 11-atom spacer using active ester chemistry and all of the sorbents were evaluated individually on a small test column. Figure 1 shows representative chromatograms to illustrate that different antibodies bind CD4 differently.

Ligand	L-71	L-83	L-92.5
Load (μg)	1400	1400	1400
Unbound	1062	1306	820
Eluted	336	55	61

Figure 1 Absorbance (A_{280}) profiles of sCD4 binding to IA column. Soluble CD4 (sCD4), at 0.1 mg mL^{-1} in *N*-(2-hydroxyethyl)piperazine-*N*-(2-ethanesulfonic acid) (HEPES) buffer at pH 7.5, was loaded at 60 cm h^{-1} at 4 °C on to a 1 × 6.4 cm IA column, preequilibrated with 0.05 M HEPES, 0.15 M NaCl, 0.01% PEG 3400 (pH 7.5). To remove nonspecifically bound proteins, the column buffer was washed with two column volumes of HEPES containing 0.5 M NaCl at the same flow rate. Bound sCD4 was eluted with 0.1 M acetic acid, 0.15 M NaCl, 0.01% PEG 3400 at 60 cm h^{-1}. The inset shows the quantities of sCD4 in various fractions determined by Bio-Rad protein determination. (Reproduced by permission of Elsevier Science from C. Jones, A. Patel, S. Griffin, J. Martin, P. Young, K. O'Donnell, C. Silverman, T. Porter, I. Chaiken, *J. Chromatogr. A*, **707**, 3–22 (1995).)

In the cases of L-92.5 and L-83 clones, the binding was restrictively tight, whereas L-71, L-77, and L-104.5 showed moderate and more tractable binding affinity. Although L-92.5 sorbent bound the highest amount of CD4, the recovery was the least of all the sorbents. On the other hand, the L-71 sorbent showed moderate binding but the recovery of sCD4 was quantitative. Thus, MAb L-71 was judged to be the most suitable candidate for immobilization to prepare an affinity sorbent to purify CD4 and a scale-up IA sorbent to purify CD4 congeners. Using this antibody as IA sorbent, recombinant proteins loaded on the column were recovered with very high yield using elution with 0.1 M acetic acid. The proteins recovered formed an electrophoretically homogeneous product and after neutralization were highly active with respect to gpl20 binding, as judged by a radioligand-bead binding assay. The sorbent was also used successfully to purify full-length CD4 in highly active form.

A large-scale IA purification process was developed for the isolation of recombinant sCD4 from *Escherichia coli* fermentations.[27] The MAb used for IA purification of sCD4 recognized a conformation-dependent epitope on the surface of domain 1 of CD4. IA chromatography was used to purify both sCD4–183, consisting of the N-terminal 183 amino acids of human CD4, and sCD4–PE40, a fusion protein consisting of the N-terminal 178 amino acids of CD4 and amino acids 1–3 and 253–613 of *Pseudomonas* exotoxin A (PE40). Relatively high recoveries of sCD4–183 and sCD4–PE40 were observed in the IA step of the purification process (71 and 79% recovery, respectively). sCD4–183 was purified from *E. coli* cell pellets using cell disruption, protein solubilization, oxidation, Q-Sepharose anion-exchange and IA chromatography steps. sCD4–PE40 was purified from cell pellets using cell disruption, protein solubilization, oxidation, Cu^{2+} immobilized metal-affinity chromatography, anion-exchange and IA chromatography steps. The immobilized MAb appeared to select for correctly folded CD4 protein, since sCD4–183 and sCD4–PE40 purified by the IA method bound HIV glycoprotein gp 120 (HIV gp 120) in vitro. The results demonstrate that immobilized monoclonal antibodies directed against conformational epitopes may be used for the rapid purification of gram amounts of correctly folded protein from mixtures of oxidized *E. coli* proteins.

4.2.2 Red Blood Cell Membrane

Molecular masses of the proteins contained in red blood cells membrane range between 20 and 200 kDa, and consequently the most common HPLC techniques used for the purification of these proteins are based on SEC (which may be used in the presence of either ionic or nonionic detergents) and, to a lesser extent, on ion-exchange or hydrophobic interaction chromatography (compatible with nonionic detergents). We have used a reversed-phase C-4 column for the separation of

Figure 2 Separation of erythrocyte membrane proteins extracted in pure acetonitrile. Inset shows SDS/PAGE of proteins loaded into the column. Vydac C-4 column (250 × 4.6 mm ID), eluted at 1.0 mL min^{-1} with an acetonitrile gradient (20–100%) in 0.1% TFA over 60 min.

membrane proteins from erythrocyte ghosts using mobile phases containing acetonitrile and 0.1% TFA. The erythrocytes were swollen by 5 mM Na_2HPO_4 isotonic solution and after several centrifugations at 3000 *g* the pellet was solubilized in two volumes of pure acetonitrile. Samples were loaded directly on the column without any other manipulation. Figure 2 shows the chromatogram obtained using a gradient of acetonitrile.

A silica-based C-4 column eluted with TFA–acetonitrile is a perfect combination for several polypeptide separations, but was considerably less suitable for membrane protein separation than a resin-based phenyl column eluted with the same mobile phase. In our case the separation obtained with Vydac C-4 may be considered excellent, better than that reported previously with a Nucleosil C-4 column[28] where only one main peak was observed. In our opinion, the better separation is related to the absence of detergent during the extraction and elution run and probably also to the better quality of resin in the column.

4.2.3 Separation of Photosynthetic Proteins from the Thylakoid Membrane of Chloroplasts

In this section we present the results of a study performed to develop a rapid and straightforward HPLC method to resolve and identify the protein components of PSI and PSII. These two large complexes, of at least 40 proteins, are present in the thylakoid membrane of chloroplasts (Figure 3) and have the main role of capturing the light and giving the necessary energy to transfer electrons from water to nicotinamide adenine dinucleotide phosphate (NADP) via the two photosystems, PSI and PSII, and a number of electron carriers.

PSII is embedded in the thylakoid membrane and contains a reaction center (core) of 21 large and smaller proteins, surrounded by a specific light-harvesting system, which is the major protein–chlorophyll *a*–*b* complex [light-harvesting complex of photosystem II (LHCII)] and minor antennas called CP29, CP26 and CP24.[29] In contrast, structural information on PSI at the atomic level is lacking.

The proteins associated with PSI and PSII have been traditionally resolved by SDS/PAGE into several closely related hydrophobic membrane proteins, typically in the range 21–40 kDa.[30] The uncertainty of the number of proteins in the complex is mainly due to the different procedures and detergents used to solubilize PSI and PSII from the thylakoid membranes and to the different methods employed in isolating and characterizing the individual membrane proteins in the complex. The antenna proteins show amino acid compositions similar in length and sequence,[31] and therefore the characterization of these proteins is performed by tedious electrophoresis and immunoblotting, which require run times of 20–30 h.[32] Traditional approaches by SDS/PAGE are not only cumbersome but also rather ineffective for evaluating differences in the relative quantity of each LHCII component. We have set up a high-performance separation technique for the resolution of thylakoid membrane proteins employing a reversed-phase Vydac Protein C-4 column containing 5-μm pores.[33]

4.2.3.1 Preparation of Photosystem I and Photosystem II

In Figure 4 are summarized the main steps to separate the PSI and PSII present in the thylakoid membrane.

Figure 3 Organization of proteins contained in the thylakoid membrane and involved in photosynthesis. (Reproduced by permission of Professor J. Barber, Imperial College, London.)

Figure 4 Separation scheme for PSII and PSI.

Chloroplasts were isolated from spinach leaves according to the method of Berthold et al.[34] with the following modifications. Leaves were powdered in liquid nitrogen and subsequently homogenized in an ice-cold 20 mM tricine buffer (pH 7.8) containing 0.3 M sucrose and 5.0 mM magnesium chloride (buffer B1). The homogenization was followed by filtration through one layer of Miracloth (Calbiochem, San Diego, CA, USA)

and centrifugation at 4000 *g* for 10 min at 4 °C. Pellets were suspended in buffer B1 and centrifuged as above. These second pellets were resuspended in 20 mM tricine buffer (pH 7.8) containing 70 mM sucrose and 5.0 mM magnesium chloride (buffer B2) and centrifuged at 4500 *g* for 10 min. Pellets containing the thylakoid membranes were then resuspended in 50 mM morpholinoethanesulfonic acid (MES) buffer (pH 6.3) containing 15 mM sodium chloride and 5 mM magnesium chloride (buffer B3) at 2.0 mg mL^{-1} chlorophyll for 15 min after adding Triton X-100 at a final ratio of 20 mg mg^{-1} chlorophyll. The concentration of chlorophyll was determined according to the method described by Porra et al.[35] The incubation was terminated by centrifugation at 40 000 *g* for 30 min at 4 °C. This pellet containing the PSII complex and corresponding to the BBY preparation described by Berthold et al.[34] was resuspended in buffer B3 containing 20% (v/v) glycerol and stored at −80 °C.

4.2.3.2 Subfraction of Photosystem II by Sucrose-gradient Ultracentrifugation PSII membranes, once isolated from thylakoid membranes, were then subjected to sucrose-gradient ultracentrifugation in order to isolate the protein components of the minor antenna system (band 2) from the major (band 3) and also from the reaction-center complexes (bands 4–5). With this aim in mind, PSII membranes were pelleted by centrifugation at 10 000 *g* for 5.0 min at 4 °C, suspended in buffer B3 at 1.0 mg ml^{-1} chlorophyll and then solubilized by adding 1% (w/v) β-DM. Unsolubilized material was removed by centrifugation at 10 000 *g* for 10 min. The supernatant was rapidly loaded on to a 0.1–1.0 M sucrose gradient containing buffer B3 and 5.0 mM β-DM. The gradient was then spun on a Kontron (Milan, Italy) Centricon T-1080 ultracentrifuge equipped with a TST 41.14 rotor at 39 000 rpm for 18 h at 4 °C. Green bands were harvested with a syringe. The SDS/PAGE analysis of these green bands revealed that band 3 contained essentially LHCII proteins, as reported previously by Bassi and Dainese.[37] Consequently, this was the purified starting material used for the HPLC study.

4.2.3.3 Separation of Photosystem II Proteins by Reversed-phase High-performance Liquid Chromatography In this study we searched for the conditions to resolve the protein components of the major and the minor antenna system of PSII either as the complex isolated by sucrose-gradient ultracentrifugation and as assembled in the grana membrane (BBY particles), using either an analytical (250 × 4.6 mm ID) or a semipreparative (250 × 10 mm ID) sized column, both packed with the same 5-μm spherical Vydac C-4 stationary phase. The use of a semipreparative sized column was needed in order to obtain an amount of purified polypeptide sufficient for peak identification by SDS/PAGE, immunoblotting, and amino acid microsequencing. The optimum separation of the protein components of the PSII antenna system was obtained by the following procedure.

The Vydac C-4 columns were preequilibrated with 38% (v/v) aqueous acetonitrile solution containing 0.1% (v/v) TFA and samples were eluted using either gradient I or II, depending on the HPLC unit employed for the separation. Gradient I consisted of a first linear gradient from 38 to 55.4% (v/v) acetonitrile in 22 min, followed by 3 min of isocratic elution with the eluent containing 55.4% acetonitrile, followed by a second gradient segment from 55.4 to 61.8% (v/v) acetonitrile in 8 min and by a third gradient segment from 61.8 to 95% acetonitrile in 1 min. Gradient II consisted of a first linear gradient from 38.0 to 61.8% (v/v) acetonitrile in 40 min, followed by a second gradient segment from 61.8 to 95% (v/v) acetonitrile in 1 min. For both gradients the last gradient segment up to 95% acetonitrile was used for washing out hydrophobic contaminants of the PSII antenna system from the column. Gradient I was used to elute either the analytical or the semipreparative column. The flow rate was 1.0 mL min^{-1} with the analytical column and 4.7 mL min^{-1} with the semipreparative column. These conditions were selected in order to maintain the same gradient shape with both columns by keeping the ratio of the gradient volume to the column volume constant.

The chromatogram displayed in Figure 5(a) shows that the material harvested from the second band of the sucrose-gradient ultracentrifugation, containing a mixture of the protein components of both the major and the minor PSII antenna system, was resolved into eight main peaks. Five of these peaks, with corresponding retention times, were also obtained on separating, under the same conditions, the material harvested from the third band of the sucrose-gradient ultracentrifugation (Figure 5b), containing essentially the protein components of the major PSII antenna system. From these data it can be inferred that the peaks labeled 1, 2, 5, 6 and 7 correspond to components present in both the sucrose bands 2 and 3, whereas peaks 3, 4 and 8 are essentially due to the component present only in the sucrose band 2, which can be tentatively identified with the minor antenna complexes CP29, CP26, and CP24.[38] Figure 5(c) shows the chromatogram of BBY injected on the column directly, avoiding the separation step by sucrose-gradient ultracentrifugation. It can be observed that upon injection of BBY directly, the protein components of the PSII major and minor antenna system are well resolved without interference from the other protein components of PSII. Therefore, the use of the crude PSII membrane preparation does not affect the resolution and retention times, while new and smaller peaks appear at longer elution times. The

Figure 5 RPHPLC separation of spinach chlorophyll *a*/*b* binding proteins contained in (a) band 2 and (b) band 3 of spinach BBY fractionated by sucrose-gradient ultracentrifugation and (c) in whole BBY, directly injected into the column. Column, Vydac Protein C-4 (250 × 10 mm ID), eluted with an increasing acetonitrile concentration gradient as described in the text. Flow rate, 4.7 mL min^{-1}; detection at 214 nm.

new peaks, observed in Figure 5(c), represent the core proteins, which are more hydrophobic and elute at higher concentrations of acetonitrile (data not shown).

In order to assign to each HPLC peak a name of the well known antenna proteins, SDS/PAGE systems employing different buffer systems and either Coomassie Brilliant Blue or silver staining followed by immunoblotting detection with antisera directed to the individual antenna proteins were performed, in addition to amino acid microsequence analysis of the material collected throughout the chromatogram.

In the case of SDS/PAGE and immunoblotting, each fraction collected from the semipreparative chromatographic separation lyophilized, were dissolved in 120 mM tris(hydroxymethyl)aminomethane (TRIS)–HCl buffer (pH 8.45), containing 120 mM dithiothreitol (DTT), 5 M urea and 4% (w/v) SDS, and then analyzed by SDS/PAGE, according to the method reported by Shaegger and von Jagon[39] (Figure 6a).

Following electrophoresis, the gels were either silver stained or transferred to nitrocellulose. Replicates were assayed with antisera directed to LHCII, CP29, CP26, and CP24[40] (Figure 6b–d). Because of the high degree of homology shared by all of the antenna polypeptides, it was essential for identification of the fractions to take into account both the immunoreactivity and the electrophoretic mobility of the SDS/PAGE bands. In TRIS/Tricine electrophoresis, antenna proteins migrate in the following order of increasing mobility: CP29 > CP26 > LHCII > CP24 and, within LHCII, Lhcb1 > Lhcb2 > Lhcb3.[41] Accordingly, the slower migrating band was detected by the anti-CP29 in peak 4 (Figure 6b), while peak 8, containing a slightly more mobile band, was recognized by anti-CP26 (Figure 6c). The anti-CP24 detected several bands (Figure 6d) but the strongest signal, with respect to the intensity of the band in the silver stained gel, was obtained with the most mobile band in peak 3. Therefore, peaks 3, 4 and 8 seem to contain CP24, CP29, and CP26, respectively. The higher hydrophobicity of CP26 agrees with the longer elution time required.

Thus, according to the migration order of increasing mobility reported above, the fastest migrating band was recognized as Lhcb3, the second fastest migrating band as Lhcb2, and the two newly resolved bands as Lhcb1 components of LHCII.

From the above data, we conclude that peak 1 does not contain protein components; peak 2, the Lhcb2 component of LHCII; peak 3, the CP24 (Lhcb6); peak 4, CP29 (Lhcb4); peaks 5 and 6, two Lhcb1 components of LHCII; peak 7, Lhcb3; and peak 8, CP26 (Lhcb5).

In order to support the identification previously assigned, the protein contained in each HPLC peak was subjected to amino acid microsequencing and compared with amino acid sequences reported in the literature for other species (data not shown). Good agrrement with the above assignment was found.

Finally, the assignment of each peak resolved by RPHPLC performed by electrophoresis, immunoblotting, and amino acid sequencing is corroborated from the values of molecular masses determined by the combined use of microbore HPLC coupled on-line with a mass spectrometer[42] equipped with an electrospray ion source (see section 5).

From the results presented, it can be inferred that the major antenna system of PSII isolated from spinach leaves contains two different Lhcb1 proteins which can be resolved by the RPHPLC system employing a 250 mm long Vydac C-4 column eluted with a multisegment acetonitrile gradient, as well as by the high-resolution

Figure 6 Gel electrophoresis and immunoblotting of each protein collected throughout the chromatographic run reported in (a). Lanes correspond to the peak labels in (a); the last lane (c) represents the LHCII from *Zea mais* used as a control. (a) SDS/PAGE of uniform polyacrylamide concentration (13%) with TRIS–Tricine system of each collected peak, which were dried and than solubilized in 4% LDS, 120 mM DTT and 120 mM TRIS–HCl (pH 8.45), containing 5 M urea. (b) Immunoblotting of the gel reported in (a) detected by using antisera directed to CP29. (c) Immunoblotting of the gel reported in (a) detected by using antisera directed to CP26. Bianchetti, R. Bassi, F. Manera, D. Corradini, *Photosynth. Res.*, **61**(3), 281–290 (1999).)

TRIS/Tricine SDS/PAGE system in gels of 15 cm length (data not shown). On the other hand, the small microsequence performed does not reveal any amino acid differences and the molecular mass measured by mass spectrometry (MS) indicates that the difference is of the order of 60–80 kDa. More experiments and a complete amino acid sequence are necessary to give an explanation for these different subpopulations of Type I. Nevertheless, the existence of more type I LHCII is in accordance with molecular genetic data reported in the literature showing that higher plants have several Lhcb1 genes encoding different Lhcb1 proteins for each species.[31] However, it is important to note that the resolution by SDS/PAGE of two Lhcb1 proteins usually requires special experimental conditions such as the use of polyclonal and monospecific antibodies,[43] dedicated electrolyte solutions, and a gel of extended length,[44] whereas using HPLC the two different subpopulations may be easily separated.

The RPHPLC method reported here, in addition to being rapid, simple, and precise, has proven to be effective at detecting differences in the protein components of LHCII isolated from different plants that might be not evidenced by denaturating SDS/PAGE, as in the case of Type I of spinach. This knowledge is expected to shed light on the composition and supramolecular organization of LHCII and may increase the understanding of the molecular mechanisms underlying the physiological adaptations of higher plants to environmental conditions.

4.2.4 Separation of Proteins Present in Photosystem I

PSI prepared from the thermophilic cyanobacterium *Synechococcus elongatus* has been crystallized and the structure determined at a resolution of 6 Å.[45] The determination of the structure of higher plant PSI has been less successful, most likely because it is a much larger complex than its cyanobacterial counterpart. The

cyanobacterial PSI complex consists of 11 subunits.[46] In the case of higher plants, although a lot of PSI genes have been identified and sequenced, there is little information on the protein, and the relationship between the gene and relative protein expressed is lacking. This is related to the fact that the molecular masses of most of these proteins range between 4 and 25 kDa, and consequently they are not well separable by SDS/PAGE.

4.2.4.1 Isolation of Photosystem I by Sucrose-gradient Ultracentrifugation Supernatants of the first purification were concentrated by ultrafiltration and then solubilized by β-DM at a final concentration of 1%. After stirring for 20 min at 4 °C, the sample was centrifuged for 10 min at 40 000 *g*, and 6-mL aliquots of the supernatant were loaded on 0.1–1 M sucrose gradients (35 mL) layered over 2 mL of 2 M sucrose, containing 5 mM Tricine (pH 7.8) and 0.03% β-DM. After centrifugation for 42 h at 28 000 rpm in an SW28 rotor (Beckman) at 4 °C, four green bands were distinguishable. The bands were collected and analyzed by SDS/PAGE.[47] The lowermost band, containing PSI-200, was diluted in 5 mM Tricine (pH 7.8) and centrifuged for 3 h at 70 000 rpm in an 80 Ti rotor (Beckman). The pellet was resuspended in 5 mM Tricine (pH 7.8) and 50 mM sorbitol, frozen in liquid nitrogen, and stored at −80 °C.

4.2.4.2 Purification of Photosystem I Core and Light-harvesting Complex of Photosystem I The pellet from PSI-200 preparation was resuspended at 0.3 mg mL^{-1} in distilled water and solubilized by 1% β-DM and 0.5% Zwittergent-16. After stirring for 20 min at 4 °C, the sample was rapidly frozen in liquid nitrogen and slowly thawed to improve the detachment between the PSI core and the light-harvesting complex of photosystem I (LHCI). Samples (1.5-mL aliquots) were loaded on a 12-mL 0.1–1 M sucrose gradient, also containing 5 mM Tricine (pH 7.8) and 0.03% β-DM. After centrifugation for 24 h at 4 °C at 41 000 rpm in an SW41 rotor (Beckman), five green bands were obtained. The bands were analyzed by SDS/PAGE.[47] The second band from the top contained all of the LHCI polypeptides and the third the PSI core particles. The fractions were frozen in liquid nitrogen and stored at −80 °C.

4.2.4.3 Separation of Photosystem I Proteins by Reversed-phase High-performance Liquid Chromatography The complete resolution of the protein components of the PSI was performed by RPHPLC as for PSII. The experiments were carried out subjecting to chromatography all proteins of PSI-200 and then separately the antenna and core proteins previously isolated by sucrose-gradient ultracentrifugation.

Figure 7 RPHPLC separation of (a) spinach LHCI proteins contained in band 2 and (b) core proteins in band 3 of PSI-200 fractionated by sucrose-gradient ultracentrifugation and (c) in whole PSI-200. Column, Vydac Protein C-4 (250 × 10 mm ID), eluted with an increasing acetonitrile concentration gradient as described in the text. Flow rate, 4.7 mL min^{-1}; detection at 214 nm.

Figure 7(a–c) compares the chromatograms obtained upon injection of (a) isolated antenna proteins, (b) the core proteins, and (c) the total PSI-200.[48]

Different gradients were used to find the optimum experimental conditions to resolve the protein components of the antenna and core complex. In the case of PSI-200, the optimum separation of all proteins was obtained with a multisegment gradient. Good complementarity between the three chromatograms is observed, indicating that the presence of all proteins in the PSI-200 system does not affect the elution time of each protein. The material harvested from the second band of the sucrose-gradient ultracentrifugation, which was previously checked by SDS/PAGE and contained a mixture

of the protein components of the PSI antenna system, is resolved into five main peaks (Figure 7a). Most of the peaks are symmetrical, but the last one at 43.4 min is broad, indicating the presence of more than one protein. In contrast, the material harvested from the third band of the sucrose-gradient ultracentrifugation, containing essentially the core protein components of PSI, shows a main peak at a long elution time of 61 min, and numerous smaller peaks. The main peak is broad and elutes at a long time, suggesting the presence of more than protein showing high hydrophobicity. Finally, in the chromatogram for the total PSI-200, five of the same peaks with retention times corresponding to those observed in Figure 7(a) are present, which are the most abundant separated proteins and allow one to hypothesize that they represent the antenna complex, although only four proteins are expected. Moreover, the main peak observed in the core complex (Figure 7b) is also observed in Figure 7(c), which may be hypothesized to contain psaA and psaB, and other smaller core peaks are underestimated when all proteins are present.

Once the optimized conditions to obtain a better separation of each component had been found, we attempted the identification of each protein contained in each peak by coupling on-line HPLC with MS (see section 5). The mass values measured by ESIMS corresponded to the molecular mass expected on the basis of the DNA sequence, allowing the assignment of each peak as reported in Figure 7(c).[49] These results corroborate the utility of on-line coupled HPLC/MS with an electrospray ion source.

Finally, the separation of both PSI and PSII may be achieved by direct injection of thylakoid membrane into the column and elution with a multisegmented gradient. All the protein components of the PSII can be well resolved without interference from the other protein components of PSI, indicating that the use of the crude thylakoid membrane preparation does not affect the resolution and retention times of each protein.

4.3 Separation of Lipoproteins

4.3.1 Preparation of Lipoprotein Fractions

Plasma or serum can be used for lipoprotein analysis. However, plasma is preferred since it can be kept cold in order to slow most enzymatic processes that degrade lipoproteins. The following procedure is commonly used to prepare lipoproteins.[15] Human blood (ca. 20–30 mL) was collected from normolipidemic males by venepuncture after 12–16 h of fasting. The blood was allowed to stand for 2–3 h at room temperature until agglutination was complete. The plasma was withdrawn after centrifugation at 1000 *g* at 15 °C for 15 min. The plasma density was adjusted to 1.225 g mL^{-1} by adding solid potassium bromide (0.3517 g KBr per milliliter of plasma). Plasma (1.225 g mL^{-1}, ca. 3–5 mL) was then placed in ultracentrifuge tubes, which were centrifuged in a swinging-bucket rotor at 200 000 *g* at 10 °C for 40 h. The lipoprotein fraction prepared by this procedure did not contain serum proteins, except for a small amount of albumin. The lipoprotein fraction in the KBr solution was dialyzed against 0.154 M sodium chloride solution.

4.3.2 Preparation of Individual High-density Lipoprotein, Low-density Lipoprotein and Very Low-density Lipoprotein Fractions

Many separations subfractionate the lipoprotein fraction of plasma. Hence each main class of lipoproteins may be collected by ultracentrifugation using a multiple discontinuous density gradient. For this purpose, human blood was collected from fasting normolipidemic healthy males in tubes containing 0.15% EDTA. The plasma was separated by centrifugation at 700 rpm at 7 °C for 20 min. A discontinuous NaCl–KBr density gradient (total volume 18.5 mL) was formed by adjusting the density of plasma to 1.30 g mL^{-1} with solid KBr and sequentially layering on the adjusted plasma salt (NaCl–KBr) solutions with densities of 1.240, 1.063, 1.019 and 1.006 g mL^{-1} and 0.5 mL of distilled water. Tubes loaded with the discontinuous density gradient were placed in a vertical rotor and centrifuged at 313 500 *g* at 7 °C for 80 min.

4.3.3 Separation of Particles and Subfractions

In an alternative to ultracentrifuge separation, the GPC mode of HPLC is the most commonly used method to separate particles such as HDL, VHDL, and LDL. Two commercial columns are commonly used: Superose 6 (from Pharmacia) and TSK-type.[50] Rigid, fast-flow agarose gels, such as Superose 6, are able to accept large sample volumes (up to 5 mL) and it is preferred for the preparation of larger quantities of plasma lipoproteins. Furthermore, multiple automated separations of lipoproteins from whole plasma may be performed with a preparative-grade Superose 6 column. Thus 2 mL of plasma are loaded and eluted with 0.9% sodium chloride and 2 mM sodium phosphate (pH 7.4). The eluent also contains 0.02% or 1% sodium azide for serum or plasma separation, respectively. VLDL, LDL, and HDL can be separated in a single run. A single separation can be completed in about 160 min. Hence the system can be used to analyze up to six different plasma samples (2 mL per sample) overnight.

Figure 8 Chromatographic profile of normal and HLP sera. Conditions: 300-mm Superose 6 column eluted with 100 mM Na_2HPO_4, 200 mM NaCl (pH 7.4) at 300 mL min^{-1}. (a) Normolipidemic sample; (b) Type IIa HLP; (c) Type III HLP; (d) Type IV HLP. Peaks from left to right: VLDL, LDL, HDL. (Reproduced by permission of *Clinical Chemistry* from W. Marz, R. Skeimer, H. Scharnagi, U.B. Seiffert, W. Gross, *Clin. Chem.*, **39**(11), 2276–2281 (1993).)

Figure 9 Stepwise elution profile of human serum lipoproteins. Column, Bio-Gel HTP DNA grade 25 × 1.0 cm ID; eluents, 25, 200, 300 and 650 mM potassium phosphate buffer (KPi) (pH 7.4), flowrate, 12.0 mL h^{-1}, sample, 2.0 mL of human serum. (Reproduced by permission of Elsevier Science from Y. Shibusawa, *J. Chromatogr. B*, **699**, 419–437 (1997).)

Fast-flow separation of plasma is also used, where lipoproteins are detected on-line at 500 nm after post-column derivatization with an enzymatic cholesterol reagent (CHOD-PAP, Boehringer Mannheim). The eluting lipoproteins and the cholesterol reagent are mixed in a chamber attached to the column outlet. The mixture is then passed through a reaction capillary and detected. Complete separation of lipoprotein fractions is usually achieved in less than 80 min. The chromatographic profiles of normal and several types of hyperlipoproteinemic (HLP) serum samples are illustrated in Figure 8(a–d). The three peaks correspond to, in order, VLDL, LDL, and HDL.[17]

Separation of lipoproteins by HPLC on TSK-type gel permeation columns is faster than on a Superose 6 column but smaller sample volumes (<300 μL) may be loaded. Furthermore, serum instead of plasma is preferred for TSK-gel HPLC of lipoproteins. With plasma there is a

danger of fibrin forming during the analysis. A further disadvantage of the TSK method is that this type of column is generally more prone to clogging than a Superose 6 column. Adsorption of lipoproteins on the support has also been noted by some workers. It was found that a combination of G4000 SW and G3000 SW eluted with 0.15 M NaCl (pH 7) was best at separating serum lipoproteins into VLDL, LDL, HDL_2 and HDL_3.[51] Separation by a TSK column allows the determination of lipids using a combination of two TSK columns and on-line enzymatic reaction. The system used two detectors. The first was placed immediately after the column and monitored protein absorbance at 280 nm. The second detector was placed after the enzymatic reactor and detected lipid absorbance at 500–600 nm.[51]

Separation of large amounts of LDLs and VLDLs from human serum may be performed by using a hydroxyapatite Bio-Gel HTP DNA grade column (25 × 1.0 cm ID) by one[52] or four stepwise elutions.[15] In the latter case, a 2-mL volume of human serum is loaded on the column and eluted with a discontinous gradient of 75, 200, 300 and 650 mM potassium phosphate buffer at pH 7.4. Figure 9 shows the elution profile of human serum obtained with a hydroxyapatite column.

Four peaks are detected, the first containing HDLs and serum proteins, the second the serum proteins, eluted at 200 mM, the third mainly LDLs, eluted at 300 mM, and the fourth VLDLs, eluted at 650 mM.

The whole lipoprotein fraction ($d < 1.21$) can be further subfractionated into VLDL, LDL and HDL by GPC.[18] Lipoprotein fractions prepared by ultracentrifugation are often used for this further chromatographic separation. In this way, the procedure is both analytical and preparative, since the isolated fractions contain no contamination from serum proteins.

Subfractionation of HDL particles accomplished by GPC gives rise to subfractions having different sizes (3.81–528 nm) and different amounts of proteins: HDL_{2a}, HDL_{2b}, HDL_{3b}, and HDL_{3c}.[18]

HDL particles may also be subfractionated by heparin affinity chromatography according to the apoE content.[20] HDLs rich in apoE were separated into five subfractions using an elution buffer with varying Mn^{2+} concentration.[19]

In the case of LDL, charge heterogeneity was demonstrated by ion-exchange chromatography. These types of separations are important since oxidatively modified LDLs have been associated with atherosclerosis.[53] LDL particles modified by Cu^{2+} were analyzed by anion-exchange chromatography using a Mono Q HR 515 column (Pharmacia).[21] Five different oxidatively modified LDLs were identified. The isolated fractions exhibited differences in density and lipid content.

4.3.4 Separation of Apolipoproteins and Isomeric Forms

The growing evidence that apolipoproteins are better markers of CHD than serum cholesterol levels[14] has increased the interest in analyzing lipoproteins according to the apolipoprotein compositions.

Affinity chromatography, which employs specific and reversible interactions between lipoproteins and ligands, is capable of separating lipoproteins on the basis of their apolipoprotein content by using nonspecific binding and IA. Heparin was successfully immobilized on to glyceryl controlled-pore glass (CPG) and used to bind specifically β-lipoproteins (apoB).[54] Serum samples applied to heparin–CPG were separated into two fractions. The unretained fraction was washed though the column with 0.1 M NaCl and the retained fraction was eluted with 1 M NaCl. Radial immunodiffusion studies confirmed the complete resolution of apoA- and apoB-containing lipoproteins. However, attempts at incorporating the heparin–CPG column into a high-performance affinity chromatography system were unsuccessful. Two types of lipoproteins have been clearly established as atherogenic, the apoB100-containing LDL and apoB48-containing chylomicron remnants.[55] Human genetic disorders resulting in increased circulating levels of either of these lipoproteins cause premature atherosclerosis. Experiments were reported to demonstrate that the NH_2-terminal region of apoB binds to heparin affinity gels with an affinity equal to or greater than that of apoB100-containing LDL.[56] In addition, apoB48-containing lipoproteins were observed to bind to heparin as well as LDL. Hence, based on these findings, it was proposed that NH_2-terminal apoB contributes to the atherogenicity of LDL and remnant lipoproteins.

Dextran sulfate is a synthetic analog of heparin, and also binds preferentially to apoB-containing lipoproteins. Commercial sulfated dextran beads from Sigma consist of sulfated cross-linked dextran and are useful for rapid (15 min) separation of apoA- and apoB-containing lipoproteins on elution of proteins by NaCl at 80 mM.

IA chromatography provides the highest specificity for separation and allows the separation of relatively large volumes (1–10 mL) of whole plasma or lipoproteins. Preparations of both polyclonal[57] and monoclonal[58] antibodies to apolipoproteins, produced using purified delipidized apolipoproteins, are commonly used as antigens. Antibodies to apolipoproteins coupled to cross-linked dextran (Sephadex) or agarose derivatives (Sepharose) serve as selective ligands for the separation of lipoproteins by IA chromatography.

Separation of apoproteins into their isomers is of interest especially for apoA and apoB, which may be performed by sequential chromatographic stages using more

IA or affinity followed by gel permeation, ion-exchange or reversed-phase techniques. In the first procedure, whole plasma is first fractionated into apoB and apoA lipoproteins by affinity chromatography on concanavalin A (con A). Further subfractionation proceeds by subsequent IA chromatography using a specific antibody: anti-apoA-II immunosorbent, which retains a fraction containing lipoprotein (A-1 + A-II) and lipoprotein A-II. Further, separation of this fraction on an anti-apoA-I immunosorber leads to the isolation of three types of apoA lipoproteins: lipoprotein A-1, lipoprotein A-II and lipoprotein (A-I + A-TI).[59]

Conventional GPC or ion-exchange chromatography on soft gel supports can be used for the preparation of large quantities (10–50 mg) of pure apolipoproteins,[60] whereas by HPLC only small amounts of sample (<5 mg) can be applied to the column but the analysis is completed within 60 min. Separation by high-performance GPC is strongly dependent on the completeness of the delipidation step, which may be performed satisfactorily with an organic solvent. However, high-performance GPC separation of HDL apolipoproteins has been achieved without prior organic solvent delipidation of the HDL fraction.[61]

GPC is often used as a preparative technique for isolating apolipoproteins derived from HDL or VLDL, while HDL apolipoproteins, apoA-I, apoA-II, and apoC, can be separated on Sephadex G-200 columns using TRIS–HCI buffer (pH 8.6) containing 8 M urea.[62] ApoC and apoE from VLDL can be isolated by Sepharyl S-200 (Pharmacia) chromatography.[62] Separation of apolipoprotein isoforms can be achieved by either ion-exchange or RPHPLC.

ApoC isoforms (C-III$_0$, C-III$_1$, and C-III$_2$) can be separated on Mono Q-HR 5/5 (Pharmacia) anion-exchange columns[63] in less than 30 min using a linear gradient of 0.15 M NaCl in TRIS–HCl containing 6 M urea (pH 8.2). This mode of apolipoprotein separation is based on differences in isoelectric points. Chromatography of VLDL and HDL apolipoproteins is performed on anion-exchange columns such as SynChropak AX300 (SynChrom IUC) and Mono Q-HR (Pharmacia).[64]

A rapid and highly efficient technique for monitoring heterogencity in apolipoproteins is the separation on the basis of differences in hydrophobicity by RPHPLC. Unfortunately, the small amounts of apolipoprotein (50–100 µg) which may be loaded, render this method qualitative but highly resolutive. Successful separations of apoA and apoC were performed on C-18 columns with a gradient of acetonitrile–water in the presence of 0.1% of TFA.[65] Figure 10 shows the separation of human apolipoproteins A-IV, A-I and E on a TSK Phenyl-5PW column.[66]

Figure 10 RPHPLC separation of delipidated rat HDL (200 mg protein) on a TSK Phenyl-5PW column. Gradient between 20 mM H_3PO_4 in water (pH 2.3) and 20 mM H_3PO_4 in 60% acetonitrile. Flow rate, 1 mL min^{-1} at 45 °C. Fractions were analyzed by SDS/PAGE and their lipoprotein contents as assessed by Comassie Brilliant Blue staining (bold bars) and by silver staining (normal) are as indicated. 5 CURRENT TRENDS

5.1 Membrane Proteins

5.1.1 Perfusion Chromatography

The advent of perfusion chromatography, which consists of matrix containing flow-through particles, has further increased the interest in using HPLC systems, especially for membrane proteins.[67] In contrast to conventional particles, the new matrix has two classes of pores. Large ''throughpores'' allow convective flow through the particles, quickly carrying sample molecules to short ''diffusive'' pores inside. By reducing the distance and therefore the time over which molecules diffuse to access the particle binding surface area, the flow rate can be increased 10–100-fold with little or no loss in resolution or capacity. Thus, once a particular mode of chromatography has been selected, it is possible to perform it by using perfusion particles. In general, the perfusion chromatography allows:

- routine achievement of high-resolution laboratory-scale separations in 30 s–3 min;
- rapid and systematic determination of the best separation method for optimum purity;
- a significant reduction in the time to process large-volume samples;
- improved yields and recoveries of biological activity through faster processing.

5.1.2 High-performance Liquid Chromatography Coupled On-line with Mass Spectrometry

Further developments in HPLC system have been achieved by coupling the outlet on-line with other instrumentation. The introduction of electrospray ion sources that are coupled with quadrupole mass filters has produced a mass spectrometer that is easily compatible with HPLC and CE, and therefore analysis and measurement of biological samples at a reasonable cost may be performed.[42,68,69] Since most MS ion sources require lower flow rates than common chromatographic levels, a split of the HPLC eluent stream must be accomplished. Such systems are highly advantageous in that they facilitate the simultaneous separation of complex mixtures along with ultraviolet (UV) adsorption and mass detection.

With regard to the separation of thylakoid proteins of the PSII, RPHPLC interfaced with MS with an electrospray ion source allows the separation and accurate molecular mass determination of the individual membrane proteins contained in each peak on the HPLC trace, in particular for the identification of the major light-harvesting complex LHCII and minor (CP24, CP26 and CP29) antenna system, whose molecular masses range between 22 and 29 kDa.[42]

Table 2 reports the comparison of the molecular mass values calculated from the protein sequence derived from the isolated genes with those determined by reversed-phase high-performance liquid chromatography/electrospray mass spectrometry (RPHPLC/ESIMS) together with the apparent molecular masses given by SDS/PAGE. The molecular mass values determined are in good agreement with the computed molecular masses of these protein based on their DNA sequences.

Thus, the assignment of each peak resolved by RPHPLC performed as above by electrophoresis, immunoblotting, and amino acid sequencing is corroborated by the values of molecular masses determined by the combined use of HPLC coupled on-line with a mass spectrometer equipped with an electrospray ion source (ESIMS). Furthermore, the resolution of two variants of type I proteins is in agreement with previous findings reporting the resolution of more than one type I protein by both high-resolution polyacrylamide gel electrophoresis[37] and HPLC[38] and is consistent with the high copy numbers of *Lhcb1* genes isolated in higher plants,[31] giving confidence in the real potential of these coupled techniques. On the other hand, the isolation of multiple copy numbers of the same gene from several higher plant species accounts for the resolution of different variants of the same proteins reported in the literature.[31]

In the case of glycoproteins, ESIMS can detect whether an oligosaccharide is O or N-linked.[70] It can also differentiate between complex, high-mannose, or hybrid forms. Moreover, this technique may be used to gain limited linkage order information using collision induced dissociation (CID) with both a single- and a triple-quadrupole mass spectrometer. In fact, in a complex map the region of the map that contains the glycopeptides can be deduced by looking for characteristic patterns in the two-dimensional (2D) plot or by the observation of oxonium ions produced by CID. The plot of m/z against retention time (contour maps) as a facile approach to the rapid 2D mapping of complex samples has some similarity to the popular 2D techniques currently used in biochemistry, such as a combination of IEF and SDS/PAGE, but offers a different combination of orthogonal separation methods. Such maps are readily available from the data generated by an HPLC/MS analysis and can give valuable information about glycosylation patterns and product consistency.

This new analytical method can be used to deduce possible carbohydrate structures by determining both the mass and elution position of individual glycopeptides.

RPHPLC/ESIMS has greatly expanded the power of peptide mapping to identify carbohydrate structures that are attached to asparagine, serine, or threonine

Table 2 Comparison between experimental and computed values of the molecular masses (Da) of the protein constituents of the PSII major and minor antenna system

Antenna proteins	SDS/PAGE: apparent molecular mass (Da)	Molecular mass (measured)	Molecular mass (expected)	
			Spinach	Other species[a]
Type 1 I	27 000–28 000	24 936	25 030	25 026 24 969 (M)
Type 1 II		24 942		25 041 24 906 (P)
Type 2	25 000–27 000	24 761		24 834 (T)
Type 3	24 000–25 000	24 323		24 285 (B) 24 308 (T)
CP 29	29 000–31 000	28 076		27 804 (B) 27 642 (T)?
CP 26	26 000–29 000	27 068		26 607 (M) 27 642 (T)?
CP 24	20 000–22 000	22 820	22 813	

[a] Plant species: P, petunia; M, maize; T, tomato; B, barley.

residues. One can use in-source CID to scan the map for regions with a high concentration of glycopeptides. Such information should prove invaluable in determining the role in biology of the carbohydrate moiety in glycoproteins and in reducing the approval barriers for the pharmaceutical use of glycosylated proteins produced by mammalian fermentation systems.

5.1.3 High-performance Liquid Chromatography Coupled On-line with Light Scattering, Ultraviolet Absorbance and Refractive Index Detectors

Since protein molecules self-associate to oligomers for specific purposes and we often have no idea whether the protein exists in solution as a monomer, dimer, or other oligomer, the possibility of determining the molecular weights of proteins or their complexes is an important step in understanding proteins and their functions. In addition to HPLC coupled on-line with a mass spectrometer, techniques of using SEC with on-line light-scattering, UV absorbance, and refractive index detectors have recently been reported.[71] Conventional SEC is a simple and fast method for estimating the molecular mass of a protein in its native form based on its elution position. However, there are several problems with this simple SEC approach. One is that the elution position depends not only on the molecular mass of the protein but also on its shape. Another problem is that the elution position will change if the protein has any tendency to interact with the column matrix. In addition, when a protein or a protein complex contains carbohydrates, the carbohydrates usually have a disproportionately large effect on its elution position, so SEC may not be able to determine its polypeptide molecular mass. However, as reported by Wen et al.,[71] by using two or more detectors proteins and glycoproteins may be easily determined.

5.1.4 Affinity Chromatography and Biosensors

Affinity chromatography, which in the past yielded success as a preparative tool, has stimulated the development of analytical applications for biomolecular recognition and most recently of molecular recognition biosensors. Affinity-based methods on other solid-phase surfaces such as blots and microliter plates have further expanded affinity-based technology. The principles of analytical affinity chromatography recently have been adapted for a nonchromatographic affinity technology, namely real-time optical biosensors for interaction analysis. As a real-time method, biosensors offer the opportunity to measure not only the equilibrium affinity constant but also the on and off rate constants for interactions of biological macromolecules.[72]

5.2 Lipoproteins

CCC is a generic name for various liquid–liquid partition chromatographic methods which are used without solid support matrices.[73] The stationary phase is retained in the column with the aid of gravity or centrifugal force. In this way the system eliminates all complications arising from the solid support. Previous studies have shown that a mixture of HDL and LDL fractions prepared by ultracentrifugation could be separated by *x*-axis ultracentrifugation.[74] Recently the complementary use of CCC was attempted for the separation of three main classes of lipoproteins. Consequentely, the fractionation of HDLs, VLDLs and LDLs may be performed by the combined use of polymer-phase CCC and hydroxyapatite chromatography without prior ultracentrifugation.[75]

In the last decade, CE has emerged as a powerful separation technique for separation of plasma apolipoproteins.[76] By adding the surfactant SDS to the separation buffer, the main apolipoproteins of HDL (apoA-I and apoA-II) and LDL (apo-B) may be separated in a single run in less than 12 min. The CE separation of VLDL apolipoproteins has also been studied. High-performance capillary isotachophoresis (ITP) of lipoproteins has been reported, which provided for rapid screening of lipoprotein abnormalities.[77]

6 COMPARISON WITH OTHER METHODS

To summarize, it is not surprising that HPLC techniques, given the wide versatility, relative ease of use and high resolution, may be considered the most valuable tool for the characterization of virtually any hydrophobic protein. New supports offer a good compromise between mechanical stability and nonspecific binding, and an excellent recovery of the protein loaded. Moreover, these matrices also have excellent chemical stability within the working range of biological separations. In this context, the use of a reversed phase C-4 column, where the interaction of proteins with the matrix is very soft, has allowed a good separation and the complete recovery of proteins when applied to the separation of photosynthetic apparatus.[33,38] In this particular case, where the protein molecular masses are similar and the amino acid sequence is sufficiently conserved, electrophoresis and immunoblotting appeared expensive and technically demanding. Moreover, for quantitative analysis, traditional approaches by SDS/PAGE are not only cumbersome but also rather ineffective for evaluating differences in the relative quantity of each component unless time-consuming antibody titration is used.[78]

Table 3 Comparison of the advantages and disadvantages of separations performed by HPLC and other methods

Parameter	RPHPLC	CZE	IEF	SDS/PAGE
Analysis time	30 min	10 min	Hours	18–24 h
Reproducibility	Excellent	Reasonable	Operator dependent	Operator dependent
Sample amount	1–50 μL	1–5 μL	1–100 μL	1–100 μL
Resolution	Good	Good	Excellent	Excellent
Sensitivity	Nanograms	Picograms	Micrograms	Micrograms
Quantitative analysis	Excellent	Good	Reasonable	Reasonable
Automation	Yes	Yes	No	No

CZE, capillary zone electrophoresis.

In Table 3 are summarized the advantages and disadvantages of separations performed by HPLC with others alternative separation systems such as SDS/PAGE, IEF, and CE. The number of reports dealing with the separation of membrane proteins by high-performance CE is still rather small. First results indicate that virtually all methods used for the separation of water-soluble proteins can also be applied to the separation of hydrophobic membrane proteins. Apart from the guidelines mentioned above, the know-how acquired in high-performance CE and in the preparative free-flow (ITP) of serum lipoproteins can be transferred to the separation of membrane proteins.[79] Recently, we have demonstrated that CZE can be successfully applied for the complete resolution of the LHCII thylakoid membrane proteins by using the neutral detergent OD at a concentration lower than its critical micelle concentration in the electrolyte solution.[80] This method was revealed to be rapid and sensitive for identifying and determining quantitatively the several components of PSII, but the RPHPLC method,[33] in addition to being rapid, simple, and precise, has proven to be effective at detecting differences in the protein components of LHCII isolated from different plants that might not be evidenced by denaturing SDS/PAGE, as in the case of many species (data not shown). In addition, the possibility of separating all protein components of the PSII major and minor antenna system in samples not subjected to sucrose-gradient ultracentrifugation, as in the case of injection of BBY, is expected to be advantageous for evaluating the relative content of the different protein components of PSII and their variation related to physiological adaptation to environmental conditions. The injection of BBY directly allows one to obtain an exact evaluation of the quantitative relationships between chlorophyll *a*/*b* binding present in PSII, avoiding fractionated separation, Coomassie Brilliant Blue staining, quantification by densitometry, and correction of the results according to the specific binding of Coomassie Brilliant Blue to isolated proteins, as required by SDS/PAGE. The use of this method in screening photosynthetic mutants and plants adapted to different environmental conditions will be useful in the elucidation of the composition and supramolecular organization of LHCII and will possibly increase the understanding of the molecular mechanisms underlying the physiological adaptations.

As shown in the application examples in section 4, all HPLC methods developed for membrane protein separations offer the further advantage of analyzing the content of each HPLC peak by a multidimensional approach. A single peak observed in the RPHPLC separation of a protein is not an indication that the protein is highly pure, because it is common for related substances to co-elute with the parent protein. The main peak can be isolated and reinjected into an alternative separation system such as an SDS/PAGE, IEF, CE, or dissimilar HPLC system, taking appropriate measures to avoid decomposition of the protein after collection from the HPLC system. If the HPLC solvent system is not compatible with the second separation system, or if suitable stability of the isolated main peak is not attainable, then the nonfractionated protein product can be subjected to one of the alternative separation procedures. On-line spectroscopic monitoring using diode-array detection can be of value in establishing peak purity in favorable cases, but usually protein spectra are too similar to provide much discrimination.

The RPHPLC/ESIMS method holds several advantages over SDS/PAGE, the conventional technique for studying membrane proteins, including better protein separation, mass accuracy, speed and efficiency. Our study has shown that RPHPLC/ESIMS is an effective method for separating and characterizing the integral membrane proteins comprising the PSII major and minor antenna system, both as isolated complexes by sucrose-gradient ultracentrifugation and as the BBY grana membrane preparation directly. In accordance with molecular genetic data reported in the literature, showing

that higher plants have several *Lhcb1* genes encoding different type I proteins for each species, two type I proteins of similar molecular mass have been resolved in spinach leaves. The experimental data are in good agreement with the molecular masses of the individual antenna proteins calculated on the basis of their nucleotide-derived amino acid sequences. In addition, the RPHPLC/ESIMS method allows the separation of protein constituents of the major and minor antenna system which are not resolved by conventional SDS/PAGE methods. Other advantages of RPHPLC/ESIMS over SDS/PAGE include the accuracy in determining the molecular mass and the higher speed and efficiency.

The use of chromatographic methods offers the possibility of combining more techniques, and therefore both SEC and RPHPLC methods will be employed to provide high-resolution, quantitative data, in addition to various spectroscopic, electrophoretic, and immunochemical procedures for more specialized purposes. Conventional electrophoretic techniques often do not directly add to the information obtained, because HPLC frequently offers better resolution of related substances. However, a key advantage of conventional electrophoretic techniques is the ability to detect virtually any protein, thereby ensuring that any unanticipated protein impurities would be detected. In developing the HPLC methods to be used in the battery of tests, one must also consider the information obtained from the other techniques and seek to understand the relationship between these sets of information. The objective of such an assessment is to obtain the maximum amount of relevant information consistent with an efficient use of analytical resources.

Concerning lipoproteins separation, it was reported in section 5 that by using CE, high separation efficiencies and short analysis times for lipoproteins can be achieved. CE exhibits advantages over HPLC for lipoprotein analysis: CE separations are faster and do not require the use of expensive columns, and CE does not suffer from slow mass transfer rates which lead to band broadening in HPLC separations of apolipoproteins. The main advantage of CE over conventional electrophoresis is speed and instrumental format, which eliminates the need for labor-intensive steps such as gel preparation and staining.

ACKNOWLEDGMENTS

I am grateful to former and present members of the research group who have contributed to much of the work presented in this review, and to Dr Anna Maria Timperio and Dr Sara Rinalducci for valuable assistance in the preparation of the manuscript. This work was supported by CE Project CIPA CT93 0202 and COST Contract ERB IC15CT 980126.

Electron spin resonance (ESR) is a powerful analytical tool used in protein and peptide biochemistry. It is used in the determination of secondary, tertiary and quaternary protein structure and associated conformational changes. Protein dynamics and the relative orientation of protein components in ordered systems can also be measured. The majority of proteins do not contain unpaired electrons whose spin transitions give rise to an ESR signal, hence necessitating the use of extrinsic probes called spin labels. Spin labels are nitroxide derivatives with a stable unpaired electron and a functional group for specific attachment to the protein (covalent or as a ligand). The most popular covalent sites are cysteine residues, which, if necessary, can be introduced into the protein structure using molecular biology techniques.

The physical basis for nearly all ESR applications is the anisotropy of the nitroxide signal and the sensitivity of the ESR spectra to various relaxation pathways. The interaction between an electron of a spin label and an external magnetic field depends on their relative orientations. The splitting and the center of ESR spectra of an oriented sample are used to determine the orientation of labeled domains. For samples with little disorder the orientational sensitivity is better than 1°. The width of the signal is proportional to the orientational disorder, which is used to measure conformational heterogeneity of proteins.

If the spin label reorientates itself on the ESR timescale (nanoseconds) then the spectral anisotropy is averaged. The extent of averaging defines the ESR line shape which is used to determine the rotational rate and anisotropy of motion. The dynamic range of ESR is very broad, rotational correlation times range from 10^{-12} to 10^{-7} s for conventional ESR and the sensitivity can be extended to slower motions (10^{-3} s) with nonlinear saturation transfer electron spin resonance (STESR). Protein (spin label) mobility is used to follow conformational changes, steric restrictions on the spin label and the formation of large complexes.

Spin labels are also sensitive to the presence of other paramagnetic species. Collisions with water and lipid-soluble relaxing agents provide additional relaxation pathways measured by changes in relaxation times. The probability of these collisions reflects the accessibility of a spin label to the relaxant. The periodic patterns along the polypeptide chain of this accessibility are used to determine the secondary and tertiary structure of proteins. In the presence of another bound spin label or a paramagnetic metal complexed by histidine residues, spectra become broadened by dipolar or exchange interactions. Both mechanisms depend on the distance between the paramagnetic centers. Thus ESR can be used to determine intra- and intermolecular distances. The range of sensitivity is 5–25 Å and there are intensive efforts to increase the upper range to >50 Å. ESR as a spectroscopic ruler is used in protein structure determination and the investigation of macromolecular assembly processes and protein folding.

The foremost limitation of spin labeling ESR is the necessity to modify a protein with a spin probe. In some cases, the spin labels may perturb protein function and therefore cannot be used for spectroscopy. However, even an unsuccessful modification that results in functional

loss identifies functional regions of proteins and as such represents successful ''mutational analysis'' experiments.

1 INTRODUCTION

A spinning electron orbiting around a nucleus is a magnetic dipole. When placed in an external magnetic field, the dipole aligns parallel or antiparallel with the external field. These two orientations of the magnet represent two energy levels, with the difference in energy levels of the electron spin proportional to the strength of the magnetic field. The electron can be excited from one level (i.e. parallel dipole orientation) to another (antiparallel orientation) by an oscillating magnetic field. The energy of the oscillating field has to match the energy difference between the two levels. For a free electron in a magnetic field with a strength of a few hundred gauss, the frequency range of the exciting field is in the microwave region of the electromagnetic wave spectrum. The resonance between the orbiting electron and the microwave field forms the basis of ESR, also known as electron paramagnetic resonance or electron magnetic resonance.

ESR is commonly used to investigate protein and peptide structure, particularly studies of molecular orientation, protein dynamics and ligand binding. Observation of a resonance requires samples containing an unpaired electron, e.g. transition metals or organic radicals. Proteins and peptides are generally not paramagnetic and therefore require the use of extrinsic probes called spin labels. Spin labels are derivatives of nitroxides, small stable organic radicals, which are covalently attached to protein side chains or to metabolic substrates. In the last decade, the development of site-directed spin labeling (SDSL), which utilizes molecular biology to introduce new labeling sites, has established ESR as a protein structural determination technique. Patterns of side-chain mobility, accessibility to quenchers and the measurement of distances between spin labels have allowed the determination of the secondary, tertiary and quaternary structure of proteins.

This article is focused exclusively on spin labeling applications in protein and peptide biochemistry. The vast literature on metalloproteins, photosynthesis and reactive radicals in biology is not discussed here, and interested readers are directed to the many excellent reviews on these topics.[1–6]

2 HISTORICAL PERSPECTIVE

The first ESR experiments were performed by Zavoisky at the University of Kazan (Russia) during the Second World War.[7] Inspired by the experiments of Gorter[8] and Rabbi et al.[9] on paramagnetic relaxation and atomic beams, Zavoisky demonstrated resonance between microwaves and the precession of Cu^{2+} ions in a magnetic field. Resonance was observed as an absorption of microwaves whenever the frequency of the oscillating microwave field was equal to the ion precession frequency.

In the decade following the Second World War, ESR was the domain of physical chemists and physicists, with the first biological applications appearing in the mid-1950s. This early work included structural studies of metalloproteins,[10] measurement of free radicals in biological tissues,[11] carbonized carbohydrates,[12] and X-ray irradiated silk and hair.[13] Assenheim provides an excellent review of this early work with intrinsic ESR signals.[14]

In 1965, McConnell introduced extrinsic spin labels designed to label proteins. Using nitroxide derivatives first synthesized in Russia,[15,16] McConnell et al. demonstrated a helix–coil transition of a polylysine peptide.[17] Since then, ESR spin labeling has been used to study conformational changes in a number of proteins modified by maleimide nitroxides, which specifically target cysteine residues. However, reliance on the naturally occurring cysteine residue was a severe limitation. The SDSL strategy developed by Hubbell in 1989 employs molecular biology to introduce new cysteines for spin label attachment. The use of SDSL to scan the protein sequence with cysteines has stimulated the resurgence of ESR as a structural biology method.

The methodology of ESR was also undergoing an evolution. In 1957, Feher invented electron–nuclear double resonance (ENDOR) spectroscopy, a combination of both ESR and nuclear magnetic resonance (NMR),[18] in which nuclear spin transitions are observed indirectly by monitoring electron spin transitions. A few years later, electron–electron double resonance (ELDOR) spectroscopy was developed by Hyde et al.[19] and Benderskii et al.[20] which allowed the measurement of spectral diffusion between distinct spin populations. The development of spin-echo instruments by Mims et al.[21] introduced time-domain ESR in the 1960s. This was followed by Fourier transform electron spin resonance (FTESR), developed independently in the 1980s by Eliav and Freed,[22] Dinse et al.[23] and Bowman.[24] The first spin label applications appeared in 1986 when Gorester and Freed performed two-dimensional (2-D) FTESR experiments to measure spin dynamics.[25]

ESR moved towards high field (high frequency) with Lebedev et al.'s construction of a 150-GHz spectrometer,[26] followed by Freed et al.'s 250-GHz spectrometer, which was based on quasi-optics. The latter instrument was used extensively to investigate spin labels

in biological systems.[27] Ultra-high-field spectrometers operating at 550 GHz now exist and their application to nitroxide labels is only a question of time.[28]

Readers interested in the history of ESR are directed to a series of historic recollections of the ESR pioneers assembled by Eaton et al.[29]

3 SAMPLE PREPARATION

3.1 Nitroxide Spin Labels

Proteins are ESR silent, with the exception of metalloproteins, and must therefore be ''labeled'' with paramagnetic probes. These probes, or spin labels, are nitroxide derivatives containing an unpaired electron in the pπ orbital of the N–O bond (Figure 1a–c). The nitroxide radical is stable owing to the presence of methyl groups on neighboring carbon atoms. To limit flexibility, the NO group is enclosed in either a six-membered piperidine or a five-membered pyrrole ring. Pyrrole rings with an unsaturated bond are the least flexible.

The unpaired electron in the pπ orbital also interacts with the spin of the nitrogen nucleus, splitting the ESR signal into resonances corresponding to different nitrogen nuclear manifolds. Thus, the number of resonant peaks depends on the nitrogen isotope, three for ^{14}N and two for ^{15}N. ^{15}N labels have the advantage of less spectral dispersion which increases the signal amplitude 1.5-fold in conventional ESR and allows for full spectral coverage in FTESR. Reduction of the nuclear manifolds also simplifies the interpretation of nuclear relaxation and accelerates computer simulations of ESR line shapes. ^{15}N labels, however, are considerably more expensive than ^{14}N and only a handful of them are available commercially.

A weaker interaction occurs between the electron spin and the hydrogen nuclei of the ring and methyl groups. Each resonance peak is split by the nuclear spin, but the splittings are unresolved, resulting in a broad peak. The broadening can be removed by the substitution of hydrogen with deuterium which increases the peak height 1.5-fold for Gaussian and 5-fold for Lorentzian lines.

Figure 1 Commonly used nitroxides: (a) six-membered piperidine ring; (b) saturated five-membered pyrroline ring; (c) unsaturated pyrrolidine ring.

3.2 Labeled Sites

Nitroxide spin labels are used either covalently as modifiers of selected amino acids or noncovalently as analogs of substrates or enzymatic cofactors. The specificity of the label is conferred by the functional group attached to the nitroxide. For example, maleimide, iodoacetamide, indanedione and α-ketone groups attached to the nitroxide moiety target cysteine residues, while lysines are modified by activated esters in Figure 2(a–d). Attachment of the nitroxides by disulfide bonds allows for reversible modification. Reduction of the disulfide bonds with a mild reducing agent yields the unmodified protein. Bifunctional spin labels with two linker groups facilitate attachment to two sites on a protein, reducing probe mobility with respect to the protein. The ability to engineer neighboring attachment sites in a protein using molecular biology is likely to increase the use of bifunctional labels.

The molecular biology revolution has had a profound impact on spin label ESR. The limitations of using naturally occurring binding sites are circumvented by the site-directed spin-labeling method pioneered by Hubbell et al.[30] In SDSL, native cysteines are mutated out and new cysteines are introduced at desired vantage points. The power of this method is best illustrated by cysteine scanning where each residue along the polypeptide chain is changed to a cysteine and labeled with nitroxide.

Noncovalent labels are used in the investigation of active sites, e.g. substrate or cofactor analogs, adenosine triphosphate (ATP) or nicotinamide adenine dinucleotide (NAD) nitroxide adducts (Figure 3a–c). The binding and function of these substrates are often not compromised by the presence of the nitroxide. Both approaches

Figure 2 Various spin labels used in covalent modification of proteins: (a) maleimide spin label; (b) methyl thiosulfonate spin label; (c) iodoacetamide spin label; (d) hydroxysuccinamide (lysines).

Figure 3 (a, b) ATP spin labels and (c) NAD spin label.

are combined in photoactivated labels with an additional azido or nitrene groups. The label is guided by a substrate analog moiety to an active site and photoactivation attaches the label covalently to the protein.

3.3 Attachment Rigidity

Spin labels are attached to a protein via one or more single bonds about which the nitroxides can rotate on a subnanosecond timescale. In studies of protein orientation and dynamics, such an independent (librational) motion is a major hindrance since it averages the orientational dependence of magnetic tensors – anisotropy. Anisotropy of magnetic tensors is the basis for ESR orientational and motional sensitivity as discussed in sections 5.1 and 5.2. The extent of probe motion is estimated by immobilizing the protein on either glass or ion-exchange beads and comparing spectral parameters such as effective splitting (in conventional ESR) or line-height ratios (in STESR) to their rigid limit values. Alternatively, the protein mobility can be reduced by increasing the medium viscosity, η. The observed spectral parameters can then be plotted against η (Perrin plots) and extrapolated to infinite viscosity. If the extrapolated values are lower than the rigid limit of the nitroxide, or if discontinuities exist in the Perrin plots, then it can be concluded that the probe moves independently of the protein.

3.4 Impairment of Function/Structure of Labeled Proteins

Covalent modification of proteins with extrinsic probes carries the danger of damaging the function of the molecule. Certain labels are innocuous at certain sites while others are not. No generalizations can be made. For example, out of 32 spin-labeled cysteine mutants of T4 lysozyme, 11 displayed intact activity and 11 had activity $\geq$50%. Modification of buried residues and residues in tertiary contacts decreased appreciably the enzymatic activity.[31] In K^+ channels, ion pumping was affected by <50% in 46 out of 66 spin-labeled mutants and very few were completely inactivated.[32] Therefore, a careful functional characterization is necessary if the objective of the study is the correlation of structure and function.

The overall global structure of a protein is generally less affected than its function by labeling. Nitroxide labels are relatively small and a labeled cysteine is not much larger than a tryptophan residue. Surface labeling has been shown to have little effect on protein folding or stability. However, when buried residues are labeled, side chains and backbone can shift to accommodate the labels and restore packing of the protein core.[33]

4 TECHNIQUES AND INSTRUMENTATION

4.1 Continuous Wave Electron Spin Resonance

4.1.1 Theory

The magnetic moment, μ, of an electron interacts with an external magnetic field just like a compass needle interacts with the earth's magnetic field. The interaction of electron spin with the field is often referred to as the *Zeeman interaction*. The energy (E) of a magnetic dipole (μ) in a static magnetic field is given by Equation (1):

$$E = -\mu H \tag{1}$$

where H is the magnetic field strength. The magnetic moment of an electron is generated by its spin (S) (Equation 2):

$$\mu = -g\beta S \tag{2}$$

with β denoting the Bohr magneton (intrinsic unit of electron magnetic moment) and g denoting the spectroscopic splitting factor (relates contribution of spin and orbital motion of the electron to its total angular momentum).

Unlike a compass needle, electron spin is quantized. For a single electron, the projection of S on the magnetic field axis S_z can only take values of $\pm 1/2$. Thus the energy levels from Equations (1) and (2) are $E = \pm(1/2)g\beta H$, resulting in an energy gap which increases linearly with the magnetic field, $\Delta E = g\beta H$ (Figure 4). An oscillating magnetic field can flip the electrons from one energy level to the other if its own energy, defined by the oscillating frequency ν, equals the energy gap. Hence, for resonance between the oscillating field (microwave) and the electron spin, the condition in Equation (3) has to be satisfied:

$$h\nu = g\beta H \tag{3}$$

The resonance condition can also be obtained by considering a spinning electron moving in an orbit around a nucleus placed in a magnetic field. From classical mechanics, the rate of change of the magnetic moment is proportional to the torque produced by the interaction of the moment and the magnetic field and given by their vector product (Equation 4):

$$\frac{\delta\mu}{\delta t} = \mu \otimes \gamma H \tag{4}$$

Figure 4 Energy level diagram of Zeeman and hyperfine interactions for a [^{14}N]nitroxide ($S = 1/2$, $I = 1$). The vertical arrows denote ESR transitions with the resulting first-derivative spectrum below.

where γ is a magnetogyric ratio (ratio of magnetic and inertia moments) characteristic of a given electron (Equation 5)

$$\gamma = \frac{g\beta}{\hbar} \tag{5}$$

where $\hbar$ is Planck's constant. The torque will force the magnetic dipole (μ) to precess around the static field at a defined frequency, the *Larmor frequency*, w, given by Equation (6):

$$w = \gamma H \tag{6}$$

Substitution of γ from Equation (5) into Equation (6) yields the resonant condition $h\nu = g\beta H$ stated in Equation (3). Applying an oscillating microwave field of the same frequency as the Larmor frequency cancels the orienting effect of the static magnetic field. The spin then rotates about an axis perpendicular to the static field direction, periodically aligning itself with or against the static field. This is equivalent to dipole (μ) flipping between the two energy levels.

The extent of microwave absorption, which defines the intensity of the ESR signal, is proportional to the difference in spin populations, N, between the upper and lower energy states. The ratio of the two populations is determined by the Boltzmann distribution (Equation 7):

$$\frac{N_{+1/2}}{N_{-1/2}} = \exp\left(-\frac{\Delta E}{kT}\right. \tag{7}$$

The difference in spin populations is increased by either increasing the magnetic field H or reducing the temperature T. For example, at 0.35 T and room temperature the population difference is 0.1% but it can be increased to 13% by reducing the temperature to 3 K. The difference between the levels decreases with absorption and an efficient relaxation pathway has to exist to restore the Boltzmann equilibrium. Relaxation pathways include the *dipolar spin–spin* relaxation – sharing of energy between electrons or nuclei – and *spin–lattice* relaxation – sharing vibrational modes with the lattice. They are characterized by relaxation times T_2 and T_1, respectively. Relaxation times are defined as the time interval between initial perturbation and when the deviation from equilibrium decays to 1/e of its initial value. The relaxation rates are additive and their sum defines the width (at half-height) of the resonance, Γ (Equation 8):

$$\Gamma = \frac{1}{\gamma}\left(\frac{1}{T_2} + \frac{1}{T_1}\right. \tag{8}$$

Faster relaxation (shorter T_1 or T_2) results in broader line widths. For paramagnetic ions, the strong coupling of spins to lattice (short T_1) produces broad lines. Lowering the temperature weakens lattice coupling (increases

T_1) and is commonly used to observe resonance of transition metal ions. The coupling of free radicals (including spin labels) to the lattice is weak, therefore spin–spin relaxation is more efficient and the line width is determined by T_2.

Electrons orbiting around a nucleus experience a small local field produced by the nuclear magnetic moment. This field enhances or counteracts the external field depending on the orientation of the nuclear dipole. This interaction between the nucleus and the electron is known as *hyperfine interaction*. Similar to electron spin, nuclear spin (I) is also quantized to $2I + 1$ levels. Since the selection rule for spin transitions dictates that the total spin quantum number can only change by 1, the hyperfine interactions lead to $2I + 1$ transitions (Figure 4). In the case of nitroxide labels, it is the nitrogen nucleus which interacts with the unpaired electron. For ^{15}N the nuclear spin number m_I is 1/2 so that two electron transitions are observed; for ^{14}N, $I = 1$ and therefore there are three electron transitions.

The resonance condition of Equation (3) is thus modified to include hyperfine interactions, A (Equation 9):

$$h\nu = g\beta H + m_I A \tag{9}$$

The hyperfine interaction between an electron and the nucleus has both an isotropic and dipolar component. The magnitude of the *isotropic splitting*, a_0, is proportional to the electron spin density on the nucleus. Since the unpaired electron is located between the oxygen and nitrogen, increasing the polarity of the medium decreases the oxygen's attraction and increases the electron density on the nitrogen. Thus, a_0 is a sensitive measure of the spin environment.

The pπ orbital of an unpaired electron is asymmetric, making the dipolar interactions of the electron and nucleus orientation dependent. For example, hyperfine interactions are stronger when the z-axis of the orbital is aligned with the magnetic field and weaker when the field is aligned perpendicular. The hyperfine interactions are best described by a second rank tensor, $\boldsymbol{A}$ (Equation 10):

$$\boldsymbol{A} = \begin{matrix} A_{xx} & 0 & 0 \\ 0 & A_{yy} & 0 \\ 0 & 0 & A_{zz} \end{matrix} \tag{10}$$

Typical values for nitroxide spin labels are $A_{xx} \approx A_{yy} \approx 7\,\text{G}$ and $A_{zz} \approx 35\,\text{G}$. The difference between the x- and y-components is small and often the hyperfine tensor is assumed to be axially symmetric.

The Zeeman interaction of the electron spin with the static magnetic field (Equation 1), is also anisotropic. Asymmetry of orbital motion in the pπ orbital results in different contributions of spin and orbital momenta and thus the g-value can also be described by a tensor (Equation 11):

$$\boldsymbol{g} = \begin{matrix} g_{xx} & 0 & 0 \\ 0 & g_{yy} & 0 \\ 0 & 0 & g_{zz} \end{matrix} \tag{11}$$

In contrast to the hyperfine tensor, the g tensor is rhombic with typical values $g_{xx} \approx 2.0085$, $g_{yy} \approx 2.0065$ and $g_{zz} \approx 2.0027$. The asymmetry of the Zeeman and hyperfine interactions defines ESR sensitivity to orientation and to rotational motion.

4.1.2 Electron Spin Resonance Spectrometer

A modern ESR instrument consists of three basic units: (a) a microwave bridge and resonator, (b) a variable field magnet and (c) signal amplification circuitry (Figure 5).

Microwaves of the desired frequency are generated by either a klystron or Gunn diode. Their intensity is adjusted by an attenuator and transmitted via a waveguide to the sample chamber/resonator. During resonance, a small amount of microwaves is reflected from the resonator and detected by a Shottky diode. To separate the reflected and incident microwaves, a circulator is placed between the attenuator and resonator. The circulator channels the microwaves in a forward direction: incident microwaves to the resonator and reflected microwaves to the detector. The bridge often contains an additional pathway – a reference arm which taps off a small fraction of the microwaves from the source – which bypasses the resonator and falls on to the detector to ensure its bias for the optimal detection of small intensity changes during resonance.

A static magnetic field is provided by an electromagnet stabilized by a Hall probe. The field is slowly swept by varying the amount of current passing through the electromagnet. In order to decrease microwave noise,

Figure 5 Block diagram of a typical ESR spectrometer.

Figure 6 Conventional ESR signals: (a) absorption, V_0; (b) first derivative V_1; (c) STESR spectrum, second derivative, 90° out-of-phase display, V_2'.

the resonance signal is encoded by modulating the static field with a small magnetic field generated by modulation coils. The modulation field sweeps periodically through the nitroxide resonance field. Therefore, the changes in microwave absorption due to resonance occur with the modulation frequency. A lock-in amplifier selects and amplifies only the signal which is in phase and in frequency with the modulation field and rejects all other microwave fluctuations as noise. The signal detected using field modulation is proportional to the changes in the microwave intensity during one cycle of modulation, i.e. the signal is the first derivative of the absorption (Figure 6a–b).

The microwave field produced by the klystron is too weak to induce any detectable absorption by the sample. Resonant cavities, loop gap resonators (LGRs) or, more recently, dielectric resonators (DRs) are used to increase the microwave magnetic field at the sample. The cavities rely on the generation of a standing wave pattern of microwaves whose intensity builds up during cavity resonance. The main drawback of cavities is the presence of an electric component of the microwave. The electric component is absorbed by ''lossy'', aqueous samples (common in biology) causing sample heating and loss of cavity resonance. To avoid this problem, sample volume is restricted to the nodal planes of the electric field, limiting the usable volume of the cavity and thus resulting in a low filling factor, η. Cavities are high-Q structures ($Q = E_{\text{stored}}/E_{\text{dissipated}}$), storing thousands of times more energy than is dissipated on the walls. High Q can only be achieved within a narrow frequency bandwidth of stored microwaves as $Q = \nu/\Delta\nu$. Small changes in the sample, cavity geometry or temperature can all cause frequency shifts and mismatching of the incident microwave with the cavity. Automatic frequency control (AFC) circuitry is employed to track the frequency of the klystron to that of the cavity. However, the AFC feedback response time limits the deadtime of signal changes in transient experiments such as stop-flow. In pulse experiments it is necessary to wait until the energy of the perturbing pulse is fully dissipated. This ring-downtime is proportional to Q; thus in the high-Q structures a longer time has to elapse before a relatively weak spin echo or free induction decay (FID) signal can be collected.

Most of these problems with cavities have been overcome by low-Q resonators such as an LGR or DR. These resonators condense the magnetic component of the microwave, separating it from the electric component. Lossy samples are no longer heated by the electric component. Small sample volumes and large filling factors offer an additional advantage especially when dealing with genetically engineered proteins which are often purified in picomolar quantities. Furthermore, fast dissipation of energy and the large bandwidths of LGRs and DRs make them suitable for pulsed and transient experiments.

4.1.3 Instrumental Variables Affecting the Electron Spin Resonance Spectrum

Two instrumental parameters influence the line shape of experimental spectra: *modulation amplitude* and *microwave power*. The amplitude of the ESR signal initially increases with the modulation amplitude (H_m) as it approaches the intrinsic line width (ΔH_{pp}). Maximum amplitude is attained at $H_m = 3.5\Delta H_{\text{pp}}$ for Lorentzian and at $H_m = 1.8\Delta H_{\text{pp}}$ for Gaussian line shapes. Any further increases in H_m result in a decrease of the signal. The broadening of ΔH_{pp} is observed well before the maximum amplitude of the signal. When $H_m = \Delta H_{\text{pp}}$, the observed Lorentzian and Gaussian widths are 25% and 15% larger, respectively. As a rule of thumb, modulation should be kept at one-fifth of the intrinsic line width when resolution or line width is of importance. The errors in line width are then <1%.

The ESR signal is proportional to the static microwave field, H_1, and hence to the square root of the microwave power ($P^{1/2}$), in the absence of saturation. When the rate of relaxation lags behind the rate of excitation and when the spin populations in the ground and excited states are equalized, the signal saturates and decreases to nil. The amplitude of the ESR signal (y) for a Lorentzian line shape as a function of the microwave field is given by

Equation (12):

$$y = \frac{y_0 H_1}{\sqrt{(1 + H_1^2 \gamma^2 T_1 T_2)^3}} \tag{12}$$

where y_0 is a field-independent parameter. Hence it is important to keep power levels well below the maximum amplitude whenever spectra are used to quantify the number of spins. Line-width distortions are less pronounced than those due to the modulation field, but at powers giving maximum amplitude, the observed line width increases 1.2 times over the intrinsic line width.

4.2 Saturation Transfer Electron Spin Resonance

4.2.1 Qualitative Theory

STESR was developed to study slower molecular dynamics with rotational correlation times (τ_r) of >200 ns.[34]

The timescale of conventional ESR is determined by the spin–spin relaxation time T_2 (nanoseconds). The ESR timescale can be extended to a longer spin–lattice relaxation time T_1 (microseconds) if a signal sensitive to spin saturation is observed. This can be done by saturating the signal with intense microwaves, creating a ''hole'' in the absorption spectrum, and subsequently observing signal recovery. When the saturating microwave is switched off (or decreased to nonsaturating levels) the signal recovers with the rate determined by the spin–lattice relaxation time, T_1. The onset of motion provides an additional relaxation mechanism: *spectral diffusion*. The saturation is relieved as the resonating-saturated spins rotate away from the resonance field and the unsaturated spins come into resonance. The ''hole'' broadens out across the spectrum and the intensity of the signal increases. The second harmonic, out-of-phase ESR signal (V_2'), collected at moderate saturation, is particularly sensitive to spectral diffusion. The line shape of V_2', in the presence of saturation, bears a strong resemblance to the absorption spectrum with the intensity lowered in the spectral regions most sensitive to the spectral diffusion (see Figure 6c).

4.2.2 Instrumental Parameters

The STESR signal is influenced by nitroxide relaxation times, spectral diffusion, spin saturation level and the modulation frequency with which the ''hole'' is observed. Hence the instrumental parameters which affect any of these must be precisely controlled. The saturating microwave field averaged over the sample volume is set to 0.25 G. The microwave power is adjusted to this level using the microwave field conversion factor (c), corrected for a filling factor (η) and dielectric losses, which lower the Q factor (Equation 13):

$$\langle H_1^2 \rangle_s = c\eta PQ \tag{13}$$

where P is incident microwave power. The power-to-field conversion factor is determined experimentally by the saturation of Fremy salt [peroxylamine disulfonate (PADS)] for which the half-saturation field is 0.1067 G.

The modulation frequency and amplitude, which determine the frequency of the stepping on- and off-resonance, i.e. the interval between burning and observing the ''hole'', must also be calibrated. Modulation broadening of a narrow line-width sample, e.g. Fremy salt, is used for this purpose. The observed line width (ΔH_{pp}) is dominated by modulation broadening when the modulation amplitude is ~10 times the intrinsic line width [$\Delta H_{pp}(0)$], i.e. $\Delta H_{pp} = H_m - \Delta H_{pp}(0)$. Commonly used values for the modulation field are 5 G and 50 kHz.

Finally, since the V_2' STESR signal is 90° out of phase (phase quadrature) with modulation, the precise phase nil must be found. An error of 1° in setting the phase quadrature can result in significant line-shape changes due to leakage of a more intense in-phase signal. The most popular phase nulling method is by interpolation of the unsaturated in-phase signal: two or three readings are taken within 15° on each side of the putative nil and the phase at which the signal is zero is found by linear interpolation. A general description of the experimental procedures and calibration can be found in Fajer and Marsh[35] and Squier and Thomas.[36] Digital post-acquisition methods have also been proposed but are not widely used.

As a footnote, protein mobilities measured by conventional ESR and STESR were independently verified by optical methods – fluorescence and phosphorescence anisotropy. Bovine serum albumin labeled with a dual probe bearing a spin label moiety and the optical probe eosin was measured using optical methods and ESR/STESR.[37] The agreement between the fluorescence/phosphorescence and ESR was excellent.

4.3 Time Domain Methods

Time domain ESR relies on the perturbation of the equilibrium magnetization by an intense microwave pulse which is then followed by one of the following: (a) conventional ESR to observe the return of magnetization to equilibrium – saturation recovery ESR; (b) refocusing of the magnetization in the xy-plane – spin-echo ESR; or (c) free induction decay (FID) of the magnetization in the xy-plane which is then Fourier transformed (FTESR).

The development of time domain ESR posed a formidable technical challenge. The microwave pulse must be short (a few nanoseconds) and strong enough to

cover a 70-G wide spectrum of nitroxides. The resonators must dissipate the pulse energy within tens of nanoseconds before the loss of magnetization coherence and the signal must be digitized with a subnanosecond dwell time owing to the short nitroxide relaxation times. Fortunately, technological advances in microwave sources, resonator design and data acquisition electronics in the last decade have facilitated development of commercial Fourier transform spectrometers and the time domain method has become increasingly popular. The various time domain ESR techniques are illustrated in Figure 7(a–c).

Saturation recovery electrospin resonance (SRESR) is a hybrid of continuous wave and pulse methods in which the pulse saturates a spin population at a desired field thereby creating a ''hole'' in the absorption spectrum (Figure 7a). The kinetics of recovery are determined by various relaxation pathways: spin–lattice relaxation, nuclear relaxation, Heisenberg spin exchange (HSE) or spectral diffusion. These competing pathways can be resolved by varying the pulse duration. SRESR has been used successfully in the determination of spin–lattice correlation times and spin exchange.

Spin-echo electron spin resonance (SEESR) uses a sequence of pulses; in Hahn echo a 90° pulse is followed by a 180° pulse t_1 seconds later (Figure 7b). The first pulse tips the magnetization into the *xy*-plane where individual spins rotate with their respective Larmor frequency, w. The difference in Larmor frequencies, which arises from different resonant fields, leads to dephasing of the magnetization in the *xy*-plane which is then refocused by the 180° pulse. Spins lagging by $\Delta w t_1$ before the refocusing pulse are now $\Delta w t_1$ ahead. At time $2t_1$, spins are brought into coherence and an echo is formed. In this way static differences in Larmor frequency due to different resonant fields or different local fields (inhomogeneous broadening) are annihilated. The dependence of the echo amplitude on time t_1 reveals Larmor frequency fluctuations that cannot be refocused by the 180° pulse. These fluctuations contain information about molecular dynamics, spin exchange and dipolar interactions. The decrease of the spin echo as a function of t_1 is a measure of the T_2 relaxation time. The decay of the echo amplitude is often recorded as a function of spectral position by stepping the magnetic field, resulting in a 2-D spectrum: an inhomogeneously broadened spectrum along the field axis and a homogeneous line shape on the t_1 axis. Since the inhomogeneous broadening often obscures a multitude of phenomena affecting ESR line width, then the ability to obtain a pure, homogeneously broadened spectrum is of considerable value.

Figure 7 Time domain ESR methods: (a) saturation recovery; (b) spin echo; (c) 2-D FTESR (ELDOR).

2-D FTESR is the most versatile technique of time domain ESR (Figure 7c). All the spins are excited simultaneously with a strong, short microwave pulse which tips the magnetization into the *xy*-plane. The length and strength of the signal determine the spectral range covered, e.g. for nitroxides with a 200-MHz spectral range, 2-kW pulses 5 ns in duration are needed.

Coherently excited spins precess about a magnetic field at their Larmor frequency. This precession can be detected as an oscillating signal in the *xy*-plane which decays in time as the spins lose coherence. This FID signal is Fourier transformed into the frequency domain to yield an absorption spectrum. Application of two or more pulses spaced by varying intervals allows sampling of spin coherences in multiple dimensions. In the simplest of these experiments, two-pulse spin-echo correlation spectroscopy (SECSY), the first pulse tips the magnetization into the *xy*-plane where the spins become frequency labeled during the evolution time t_1. A second pulse reverses the magnetization during the collection time t_2, canceling inhomogeneous broadening. Fourier transformation with respect to t_1 and t_2 yields an absorption spectrum along the f_2 axis and a homogeneous line width along the f_1 axis. Thus SECSY is an FTESR equivalent of field-stepped SEESR. The isolation of the homogeneous line shapes out of an inhomogeneously broadened spectrum is used to study molecular dynamics.

Three pulse sequences are used in 2-D ELDOR experiments (e.g. Figure 7c). The first pulse creates a transverse magnetization in the *xy*-plane which evolves for time t_1. The second pulse stores this frequency encoded magnetization along the *z*-axis allowing for

Figure 8 2-D ELDOR of PD-TEMPONE. In addition to autopeaks occurring at $f_1 = f_2$, there are off-diagonal cross-peaks due to HSE.[25] (Reproduced with permission from J. Gorcester, J.H. Freed, *J. Phys. Chem.*, **88**, 4678–4693 (1986).)

magnetization transfer to take place during mixing time T_M. A third pulse transforms the magnetization back into the xy-plane where it is observed during time t_2. Magnetization transfer changes the resonant frequency of a spin from f_a to f_b, creating an off-diagonal cross peak at (f_a, f_b) (Figure 8). The time evolution of the amplitude of the cross peak, measured by varying T_M, is used to determine the time course of magnetization transfer. The biophysically relevant phenomena causing magnetization transfer include HSE, modulation of dipolar interactions, nuclear flips and, most importantly, spectral diffusion due to rotational motion.

5 APPLICATIONS OF SPIN LABELING

The orientational difference of magnetic interactions (referred to anisotropy) forms the basis of spin labeling techniques in biological research. In the absence of motion, each field position corresponds to a defined orientation of the label with respect to the field. The intensity of the signal at a particular field position is directly proportional to the population of molecules with that given orientation. Hence an ESR spectrum can be used to determine the range of orientations present in a sample. Partially or fully averaging the g- and hyperfine tensor anisotropy results in spectral line shapes determined by the frequency and amplitude of molecular motion. ESR can also be used to measure intra- and intermolecular distances. The presence of paramagnetic centers in the vicinity of spin labels modulates spin relaxation pathways in a distance-dependent manner. In this section we shall discuss how ESR is used in the investigation of molecular orientation, molecular dynamics, ligand binding, intra- and intermolecular distance measurements and the determination of various levels of proteins structure.

For each of these applications a qualitative description of the physical principles allowing for these measurements will be given, followed by examples. More extensive reviews of these topics can be found in a monograph by Lichtenstein,[38] a series edited by Berliner and Reuben[39,40] and separate reviews by Hubbell et al.,[41–43] Marsh and Horvath,[44] Millhauser et al.[45,46] and, most recently, Hustedt and Beth.[47]

5.1 Protein Orientation

5.1.1 Orientation of a Single Molecule

The anisotropy of the Zeeman and hyperfine interactions confers orientational sensitivity to ESR spectra. Nitroxide spin labels with a z-axis parallel to the magnetic field generate a spectrum with a splitting of 70 G. Spins oriented perpendicular to the field display a splitting of 14 G (Figure 9).

The center position of the spectrum, determined by the g-tensor, is sensitive not only to the position of the z-axis but also to the orientation of the x- and y-axes. At 9 GHz the center is shifted 5 G downfield (left) for a spin with its y-axis aligned with the magnetic field and another 4 G for spins with x-axis parallel to H_0 (Figure 9).

The effective g- and hyperfine splitting tensors for a spin placed at an arbitrary polar angle (θ, ϕ) with respect to the field are given by Equations (14) and (15), respectively:

$$g(\theta, \phi) = g_{xx} \sin^2\theta \cos^2\phi + g_{yy} \sin^2\theta \sin^2\phi + g_{zz} \cos^2\theta \tag{14}$$

Figure 9 Orientational sensitivity of ESR spectra. Splitting of the spectrum changes when the z-axis of nitroxide rotates with respect to the magnetic field. The center of the spectrum changes when nitroxide rotates about any axis.

$$A^2(\theta,\phi) = A_{xx}^2 \sin^2\theta\cos^2\phi + A_{yy}^2 \sin^2\theta\sin^2\phi + A_{zz}^2\cos^2\theta \quad (15)$$

It follows, then, that the resonance field for a given orientation (θ, ϕ) is given by Equation (16):

$$H_{\text{res}}(\theta,\phi,m_{\text{I}}) = \frac{h\nu}{\beta g(\theta,\phi)} + m_{\text{I}}A(\theta,\phi) \quad (16)$$

Equation (16) describes the orientational resolution of ESR line shapes: a spin with a specific orientation can be found at a defined position along the field axis. The ESR intensity at any field position is directly proportional to the number of spins at the orientation defining H_{res}. An ESR spectrum can also be considered as an orientational distribution function, $N(\theta)$. $N(\theta)$ is approximated by an orthonormal set of spherical harmonics and has been developed and applied to samples with cylindrical and planar symmetry.[48,49] Alternatively, the orientation can be modeled in terms of a Gaussian distribution with a width $\Delta\theta$ and center θ_0 (Equation 17):

$$\rho(\theta) = \exp\ -\ln 2\frac{(\theta-\theta_0)^2}{\Delta\theta^2} \quad (17)$$

The ESR spectrum, $Y(H)$, is created by calculating a resonance field H_{res} for every θ within the Gaussian distribution of orientations and placing a Lorentzian first derivative line width at H_{res} with the intensity weighted by $\rho(\theta)$ (Equation 18):

$$Y(H) = \rho(\theta)\frac{(H-H_{\text{res}})\Delta H_{\text{pp}}}{[(H-H_{\text{res}})^2 + \Delta H_{\text{pp}}^2]^2} \quad (18)$$

where the peak-to-peak width of the Lorentzian (ΔH_{pp}) is defined by the spin–spin relaxation time, T_2 (Equation 19):

$$\Delta H_{\text{pp}} = \frac{2}{\sqrt{3}\gamma T_2} \quad (19)$$

ESR is one of the very few biophysical techniques directly sensitive to orientational disorder. The spectra in Figure 10(a–c) illustrate this sensitivity. As the width of the Gaussian distribution increases, the ESR resonances broaden to a powder pattern limit which is characteristic of isotropically disordered spins.

In summary, the parameters describing orientational distribution (axial, azimuthal angles and their disorder) can be obtained from spectral parameters: spectral splitting, center of the spectrum and the line width respectively. This can be achieved either by graphical methods or from the automated fitting of full spectral line-shape parameters. Graphical methods compare the effective splitting and width of the resonance to graphs obtained from computer simulations. The automated method allows modeling of more complex bimodal distributions, in both θ and ϕ, and can be linked to standard fitting routines such as Levenberg–Marquardt[50] or Simplex.[51]

Figure 10 Broadening of the spectra with increasing disorder: Gaussian disorder of (a) $\pm1^\circ$ and (b) $\pm5^\circ$ and (c) completely disordered (isotropic) distribution.

5.1.2 Macromolecular Assemblies

Of considerable interest is the orientation of molecules within macromolecular assemblies, e.g. proteins within lipid membranes or contractile proteins in the muscle

Figure 11 Definition of (a) Eulerian angles α, β and γ; (b) Eulerian transformations of the spin label orientation through the protein (myosin head); sample (fiber) frame of reference into the laboratory frame (magnet).

fibers. If the assembly of proteins is ordered and oriented at a specific angle with respect to the magnetic field, the orientational distribution of the labeled components of the assembly can be easily determined. The spectra of such samples oriented with the symmetry axis parallel to the field are the same as for a single spin (Equation 18). When the orientation of the spin label with respect to the protein is known, the ESR spectra are interpreted in terms of the orientation of the labeled domain with respect to the assembly which is of biological interest. This is achieved using *Eulerian transformations* between three frames:[52,53] *molecular* frame (defining orientation of the label within the protein), *sample* frame (orientation of proteins within the assembly) and *laboratory* frame (orientation of the sample in the magnetic field) (Figure 11a and b).

The ESR spectra are simulated taking into account the orientational distribution in each of the frames. The magnetic tensors are rotated from molecular to laboratory axes using directional cosine matrices (L) according to Equation (20):

$$A_{\text{lab}} = L^{\tau}_{\text{mol}} L^{\tau}_{\text{sam}} L^{\tau}_{\text{lab}} A_{\text{NO}} L_{\text{lab}} L_{\text{sam}} L_{\text{mol}} \qquad (20)$$

where L_{mol}, L_{sam} and L_{lab} are cosine matrices defined in Equation (21) for each of the Eulerian transformations and L^{τ} is their transpose:

$$L = \begin{matrix} \cos\beta\cos\alpha\cos\gamma - \sin\alpha\sin\gamma & \sin\beta\sin\alpha\cos\gamma + \cos\alpha\sin\gamma & -\sin\beta\cos\gamma \\ -\cos\beta\cos\alpha\sin\gamma - \sin\alpha\cos\gamma & -\cos\beta\sin\alpha\sin\gamma + \cos\alpha\cos\gamma & \sin\beta\sin\gamma \\ \sin\beta\cos\alpha & \sin\beta\sin\alpha & \cos\beta \end{matrix} \qquad (21)$$

The resonant field for each spin packet is calculated as shown in Equation (22):

$$H_{\text{res}} = \frac{h\nu}{\beta g_{zz}} + m_{\text{I}}\sqrt{A^2_{xz} + A^2_{yz} + A^2_{zz}} \qquad (22)$$

Note that the subscripts of the g- and hyperfine tensors in Equation (22) denote elements in the laboratory frame.

5.1.2.1 Protein Orientation in Membranes The Eulerian transformation approach was introduced by Griffith et al. to determine lipid orientation in membrane bilayers. The orientation of the spin label nitroxide with respect to the lipid molecule is well defined. A stack of lipid membranes is tilted with respect to the magnetic field at a known angle, and the spectra can be defined solely by the orientational distribution in the sample frame of reference (Ω_{sample}).[52,54]

Membrane-bound proteins are investigated in a similar manner. The orientation of a spin-labeled ligand of the

erythrocyte anion transporter, Band 3, was determined by flowing red blood cells into thin, flat, sample cells. The flow shear oriented the red blood cells parallel to the flow and the sample cell was rotated both parallel and perpendicular to the field in order to vary Ω_{lab}.[55] A global analysis of the tilt series resulted in a full description of the label orientation with respect to the normal membrane axis. The derived spin label orientation was found to be consistent with orientation results determined independently by analyzing the anisotropy of motion.

5.1.2.2 Muscle Proteins Similar approaches have been used to describe the orientation of various muscle proteins. Force generation in muscle is believed to be brought about by the reorientation of the myosin cross bridges. Since ESR is sensitive to the orientation of the proteins, muscle field proved to be a fertile ground for ESR applications. Muscle fibers form a naturally ordered assembly with the fiber axis defining the cylindrical symmetry required for ESR. Proteins can be labeled directly in muscle cells or labeled as isolated components and exchanged for corresponding unlabeled proteins in the muscle sample. These include most of the thin filament proteins – actin, troponin C (TnC), troponin I (TnI) and tropomyosin – and also the thick filament components – myosin heavy chain, regulatory light chain and essential light chain. The orientation of many of these components has been extensively studied as a function of the intermediate states of the acto-myosin cycle and also during muscle activation. Thomas and Cooke have established that in the absence of ATP, myosin heads attach themselves strongly and stereospecifically to actin. Muscle relaxation, in the presence of ATP, produced disorder consistent with head detachment and Brownian motion.[56] Subsequent studies using various nucleotide analogs to trap the intermediate adenosine triphosphatase (ATPase) states have revealed a sequence of orientational changes of the catalytic domain: a nonstereospecific attachment of transient, weakly bound heads followed by an equally large orientational disorder of the strongly attached heads in the prepower stroke state.[75,76] Force generation was associated with the disorder-to-order transition. The postpower stroke state, with the hydrolysis product adenosine diphosphate (ADP) in the active site, showed a local domain heterogeneity, but overall the catalytic domain was well oriented, $\Delta\theta \pm 8^\circ$ (Figure 12). Release of ADP (rigor state) resulted in a slight change in the twist and the tilt angle of the heads.[77] During isometric contraction, when most of the myosin heads should be in the prepower stroke state (immediately prior to the rate-limiting step of the cycle), no species were observed at a different angle to that of the postpower stroke heads.[102] These findings excluded a simple model in which the catalytic domain (accounting for most of the myosin head mass) generates a force while rotating by 45° from one well-defined angle to another.

Figure 12 Orientation of catalytic domain of myosin head in the intermediate stages of the contractile cycle. As the head progresses through the cycle, the dynamic disorder is continually diminished, culminating in the disorder-to-order transition associated with force generation.

A different story emerged when the labels were placed in the regulatory domain of the myosin head. Two distinct populations, centered 36° apart, were observed in contraction (predominantly prepower stroke heads), whereas in rigor, only one population was observed.[57] Clearly, the rotation of the head is limited to the regulatory domain with the catalytic domain shifting from a disordered to ordered structure.

The disorder-to-order transition was also found for other muscle proteins. For example, spin-labeled TnC is well ordered prior to Ca^{2+} activation but becomes disordered in the presence of Ca^{2+} or activating myosin heads.[58] The loss of stereospecific, protein–protein interactions is reflected by changes to the conformational homogeneity and is the basis of many molecular mechanisms. ESR, with its capacity to see directly both the ordered and the disordered populations, complements more popular methods such as X-ray crystallography or electron microscopy image reconstructions which ignore disorder.

5.2 Protein Dynamics

5.2.1 Sensitivity of Conventional Electron Spin Resonance

Conventional ESR is used to study molecular dynamics on the nanosecond timescale. This timescale corresponds to motions of peptides and small proteins, or the mobility of labels on the surface of large proteins. Sensitivity of the ESR signal to motion arises from rotational modulation of the magnetic tensor anisotropy. The anisotropy

Figure 13 Two-site exchange between environments giving rise to two resonances separated by Δw. Increased rate of exchange initially broadens the resonances then averages their resonant frequencies.

of Zeeman or hyperfine interactions results in different resonant fields for different spin orientations. Therefore, rotational motions which change the spin label orientation will modulate the ESR line shape. This can be explained by using a two-site exchange example: two spins, A and B, resonate with frequencies w_A and w_B and exchange their positions at a rate $1/\tau_{ex}$. When the exchange rate is significantly slower than the difference in resonant frequencies ($1/\tau_{ex} \ll \Delta w^0_{AB} = w_A - w_B$, slow exchange), the spectrum consists of resonances A and B centered at w_A and w_B, respectively, and the line widths are determined by T_2 (Figure 13). The effective relaxation rate $1/T_2^{eff}$ is the sum of the intrinsic $1/T_2$ rate and the exchange rate $1/\tau_{ex}$. When the exchange frequency increases, the line widths start to broaden. Further increase of the exchange rate causes partial averaging of the resonance positions. The observed difference in resonant frequencies is reduced according to Equation (23):

$$\Delta w_{AB} = \Delta w^0_{AB} \sqrt{1 - \frac{8}{\tau_{ex}^2 \Delta w^0_{AB}}} \tag{23}$$

For exchange rates faster than the difference in resonant frequencies ($1/\tau_{ex} \gg \Delta w_{AB}$, fast exchange), the two resonant peaks coalesce into one peak at the average frequency (assuming equal populations of A and B) (Figure 13). The line width is determined by the effective relaxation time, T_2^{eff}, with contributions from T_2 of species A and B and the exchange broadening (Equation 24):

$$\frac{1}{T_2^{eff}} = \frac{1}{T_{2A}} + \frac{1}{T_{2B}} + \Delta w^2_{AB} \frac{\tau_{ex}}{8} \tag{24}$$

In other words, at the fast exchange limit ($1/\tau_{ex} \gg \Delta w_{AB}$), the contribution of the exchange rate to line width disappears and the spectrum consists of a single peak at $1/2(w_A + w_B)$ with an average line width of $1/T_{2A} + 1/T_{2B}$ (Figure 13).

The above considerations generally hold true for any spins exchanging between different environments such as different local magnetic fields, dipolar interactions or association with different macromolecular assemblies. Spin label reorientation with respect to the magnetic field is also a form of exchange where the rotational correlation time τ_r is the exchange rate and the anisotropy of the g- and hyperfine interactions defines the frequency difference. At X-band, $\Delta w = (A_{zz} - A_{xx})/\hbar = 500\,\text{MHz}$ or $(g_{xx} - g_{zz})\beta H/\hbar = 185\,\text{MHz}$.

As for the two-site exchange discussed above, various motional regimes of ESR can be defined: *fast* ($\tau_r \approx 10^{-11}$–10^{-9} s), *slow* ($\tau_r \approx 10^{-9}$–2×10^{-7} s) and *very slow* ($\tau_r > 2 \times 10^{-7}$ s). Fast and slow motion are of the order of T_2 (15–30 ns) for electron spin and have visible effects on conventional ESR spectra which measure the transverse component of magnetization. The very slow motions do not affect transverse magnetization, but they do affect longitudinal magnetization which decays with T_1 (1–15 μs). These slow motions can be detected (indirectly) using saturation transfer, pulsed ELDOR or saturation recovery ESR.

5.2.1.1 Fast Motion ($\tau_r \approx 10^{-11}$–10^{-9} s) In the fast motional regime, the motion completely averages the anisotropy of the g- and hyperfine tensors. The rotational rate is obtained from the line width broadening using Redfield's perturbation theory.[59] The broadening itself is a function of the nuclear quantum spin number as different nuclear manifolds have varying anisotropy values (Equation 25):

$$\Delta H(m_I) = A + Bm_I + Cm_I^2 \tag{25}$$

The coefficient A is equal to homogeneous broadening and coefficients B and C assure differential broadening of lines belonging to different nuclear manifolds. These coefficients are obtained from the line widths of the Lorentzian lines according to Equations (26) and (27):

$$B = \frac{\sqrt{3}}{4}\Delta H(0) \left\{ \overline{\frac{V(0)}{V(+1)}} - \overline{\frac{V(0)}{V(-1)}} \right\} \tag{26}$$

$$C = \frac{\sqrt{3}}{4}\Delta H(0) \left\{ \overline{\frac{V(0)}{V(+1)}} + \overline{\frac{V(0)}{V(-1)}} - 2 \right\} \tag{27}$$

where $V(m_I)$ is the peak-to-peak height of a given nuclear manifold resonance and $\Delta H(0)$ is the peak-to-peak line width of the central line.

Factors B and C are equal for isotropic motion and τ_r^{iso} is calculated directly from Equations (28) and (29):

$$\tau_B^{iso} = -1.22 \times 10^{-9} B \tag{28}$$

$$\tau_C^{iso} = 1.19 \times 10^{-9} C \tag{29}$$

where B and C are expressed in gauss and τ in seconds.[61]

In the case of anisotropic motion, $B \neq C$, and the rates of rotation about the nitroxide z-, x- and y-axes are different. The ratio of C and B can be used to define the anisotropy as the coefficients are independent of the rate of motion. Various models of anisotropic motion are considered in excellent reviews by Marsh[61] and Beth and Robinson.[67] If the molecule is diffusing in an isotropic medium, then the rotational correlation times about the nitroxide z-axis ($\tau_\parallel$) and about an axis perpendicular to z($\tau_\perp$) are given by Equations (30) and (31):

$$\tau_\parallel = \frac{2\tau_{20}\tau_{22}}{3\tau_{20} - \tau_{22}} \tag{30}$$

$$\tau_\perp = \tau_{20} \tag{31}$$

where τ_{20} and τ_{22} describe spin relaxation and are related to the anisotropy of the magnetic interactions (Equations 32 and 33):

$$\tau_{20} = \frac{1.11 \times 10^{-7}}{H\Delta A} \frac{5(\delta A)B - 8(\delta g)HC}{\Delta g \delta A - \delta g \Delta A} \tag{32}$$

$$\tau_{22} = \frac{3.69 \times 10^{-8}}{H\delta A} \frac{8\Delta g HC - 5\Delta A B}{\Delta g \delta A - \delta g \Delta A} \tag{33}$$

where ΔA and δA are given by hyperfine anisotropy (Equations 34 and 35):

$$\Delta A = A_{zz} - \tfrac{1}{2}(A_{xx} + A_{yy}) \tag{34}$$

$$\delta A = \tfrac{1}{2}(A_{xx} - A_{yy}) \tag{35}$$

with equivalent equations for g-anisotropy. The indices in Equations (34) and (35) are permutated to calculate the values of $\tau_\parallel$ and $\tau_\perp$ for the rotation about the x- and y-axes of the nitroxide.

The above equations hold for anisotropic motion about a specific nitroxide axis in an isotropic medium. An additional complication arises when diffusion takes place within a strongly orientating potential such as in a lipid membrane, or within the steric confines of a protein. The field position of resonances now depends on the amplitude of motion, which defines the time average of available angular space; e.g. if the nitroxide can move only within an angular cone, then only the resonances corresponding to the orientations within the cone are averaged. Motionally averaged spectra are described in terms of order parameters (S) – time averages of the direction cosines of the diffusion axis with respect to the local director axis. For an isotropic diffusion within the cone angle θ_c, components of an ordering tensor are given by Equations (36) and (37):

$$S_{zz} = \tfrac{1}{2}(\cos^2\theta_c + \cos\theta_c) \tag{36}$$

$$S_{xx} = S_{yy} = -\tfrac{1}{2} S_{zz} \tag{37}$$

S_{zz} and S_{xx} are used to define the motionally averaged magnetic g-tensors $g_\parallel$ and $g_\perp$ in terms of its average value g_0 and the anisotropy Δg and δg (Equations 38 and 39):

$$g_\parallel = g_0 + \frac{2}{3}\Delta g S_{zz} + \frac{2}{3}\delta g(S_{xx} - S_{yy}) \tag{38}$$

$$g_\perp = g_0 - \frac{1}{3}\Delta g S_{zz} - \frac{1}{3}\delta g(S_{xx} - S_{yy}) \tag{39}$$

with equivalent expressions for the effective hyperfine splitting $A_\parallel$ and $A_\perp$. The latter two are resolved in the experimental line shapes; see Figure 14. Thus S_{zz} of the nitroxide z-axis can be easily obtained from Equations (38) and (39) and the corresponding cone angle from Equation (36).

5.2.1.2 Slow Motion ($\tau_r \approx 10^{-9}$–2×10^{-7} s) For $\tau_r >$ 2 ns, Redfield's theory does not hold. The equation of motion for an electron spin is solved using a stochastic Liouville equation (SLE), developed by Schneider and Freed.[60] Although the description of the SLE approach is beyond the scope of this article, one can rationalize the effect of slow motion on ESR spectra in terms of the two-site exchange. The low- and high-field extremes of the powder spectra correspond to nitroxides lying with the z-axis parallel to the magnetic field. Rotation (i.e. exchange with any other orientation) results first in an exchange broadening of the line width and then partial averaging of the anisotropy. Line width and effective splitting are

Figure 14 Definition of the parallel and perpendicular hyperfine splitting for calculation of order parameters.

used to determine τ_r (Equations 40 and 41):

$$\tau_r = a'_m \left(\frac{\Delta H_m}{\Delta H_m^R - 1} \right)^{b'_m} \quad (40)$$

$$\tau_r = a \left(1 - \frac{A'_{zz}}{A_{zz}^R} \right)^{b} \quad (41)$$

where ΔH_m and A'_{zz} are the line widths at half-height and hyperfine splitting, respectively, and the superscripts denote their rigid limit values. Coefficients a'_m, b'_m, a and b are calculated from SLE simulations. Their precise values depend on the motional model used for the simulations. For a Lorentzian line width $\delta = 3.0\,G$ and isotropic Brownian diffusion, $a'_{m=1} = 11.5\,ns$, $b'_{m=1} = -0.943$, $a'_{m=-1} = 21.2\,ns$, $b'_{m=1} = -0.778$, $a = 0.54\,ns$ and $b = -1.36$. Values for different line widths or motional models can be found in Marsh.[61] It should be noted that the calculated τ_r values depend strongly on the chosen rigid limit values. A user-friendly simulation and optimization program based on the SLE was developed by Budil et al.[50] Sensitivities of the conventional ESR and STESR spectra are illustrated in Figure 15(a) and (b).

Figure 15 Sensitivities of (a) the conventional ESR spectra and (b) STESR spectra.

Examples. Side-chain and polypeptide backbone dynamics are determined using the above formalism. Spin labels attached to the surface of small α-helical peptides exhibit subnanosecond motions observed by ESR which compare well with motions predicted by molecular dynamics simulation programs.[45,62] Scanning of the label position along a peptide length reveals a V-shaped gradient of the label mobility. The cone angle for random motion in the middle of the peptide was half the value found at either terminus. Interestingly, the C-terminus was found to be more flexible than the N-terminus, which explains the decreased stability of the C-terminus as compared with the N-terminus in α-helices.[45,46] Backbone dynamics observed in isolated peptides are further modulated by tertiary interactions. A survey of 30 cysteine mutants of T4 lysozyme with spin labels at various structural sites (on the surface of helices, within the helix termini, interhelical loops, buried sites and sites involved in tertiary contacts) revealed a characteristic pattern of spin label mobility in relation to the secondary structure of the protein.[31] When the second moment of the spectrum (defined as the reciprocal

Figure 16 Reciprocal of the square of the splitting versus reciprocal of the central resonance line width. The spectral parameters cluster according to the labeled protein structural elements.[31] [Reprinted with permission from H.S. McHaourab, M.A. Lietzow, K. Hideg, W.L. Hubbell, *Biochemistry*, **35**, 7692–7704 (1996). Copyright 1996 American Chemical Society.]

of maximum splitting squared) is plotted against the reciprocal of the central field line width ($\Delta H_{m=0}^{-1}$), sites in similar environments are clustered together (Figure 16). The clustering reflects the degree of motional restrictions, with the second moment related to the averaging of the hyperfine anisotropy and the central line width to the averaging of the *g*-tensor. When motional restrictions increase, the averaging decreases and both the second moment and the line width of the resonances increase. Hence the second moment and line width can be used as semiempirical diagnostic tools to evaluate the secondary and tertiary structure of a labeled site.

5.2.1.3 Very Slow Motion ($\tau_r > 10^{-9}$ s) When $\tau_r >$ 100 ns, conventional ESR line shapes are no longer sensitive to motion. The rate of angular exchange is too small to affect the hyperfine or *g*-anisotropy and the line shapes become insensitive to very slow motions. To study these biologically important motions, a related ESR technique was developed, STESR.

Isotropic Motion. In the presence of power saturation, the second harmonic out-of-phase (V_2') line shape resembles an absorption spectrum (Figure 6c), with the intensity reflecting the effective relaxation at that point. Since effective relaxation is related to spectral diffusion and spectral diffusion is a function of the rotational correlation time, the V_2' line shape reflects rotational mobility. The rate of spectral diffusion (τ_{sd}) is a function of the resonant field H_{res}. Some field positions are more sensitive to angular rotation than others and $\partial H_{res}/\partial\theta$ varies across the spectral line shape. For instance, the rate of spectral diffusion is zero at the turning point $H^* = H_{res}(\theta = 0^\circ)$, but increases in the intermediate fields (Equation 42):

$$\tau_{sd}(H_{res})^{-1} = \left(\frac{8}{3\pi^2}\right)\left(\frac{\partial H_{res}}{\partial\theta}\right)^2 T_2^2\tau_r^{-1} \qquad (42)$$

To the first approximation,[63] the change of the signal intensity (I) at any field position is proportional to the change of the spin–lattice relaxation time due to spectral diffusion (Equation 43):

$$I(H_{res}) = I_0(H_{res})\frac{T_1^{eff}(H_{res})}{T_1} \qquad (43)$$

where I_0 is the rigid limit intensity in absence of motion and T_1^{eff} is the intrinsic T_1 modified by spectral diffusion according to Equation (44):

$$T_1^{eff}(H_{res}) = T_1^0\frac{1 + (I_0(H_{res})/T_2)T_1^0\tau_{sd}(H_{res})^{-1}}{1 + T_1^0\tau_{sd}(H_{res})^{-1}} \qquad (44)$$

Since T_1^{eff} is a function of the field position (spin angle with respect to field), it is customary to define the line height at precise positions in the spectrum: L'', C' or H'' at $\theta = 35^\circ$ (two-thirds of the way between resonant field corresponding to $\theta = 90^\circ$ and $\theta = 0^\circ$) and normalize it to the intensity at H^* (L, C and H positions) for which spectral diffusion is zero.

By substituting Equation (44) for the effective relaxation rate in Equation (43) a semiempirical expression for the P'/P ratio dependence on τ_r is obtained (Equation 45):

$$\frac{P'}{P(H_{res})} = \frac{I_0(H_{res})}{I_0(H^*)}\frac{1 + a/\tau_r}{1 + b/\tau_r} \qquad (45)$$

The parameters a, b and $I_0(H_{res})/I(H^*)$ can be estimated from Equations (42) and (44) by numerically evaluating sensitivity $\partial H_{res}/\partial\theta$ at each spectral position. In practice, these values are obtained from fits to the experimental curves of line-height ratios from spectra of molecules undergoing Brownian diffusion with a known τ_r. Spin-labeled hemoglobin or bovine serum albumin tumbling in media of a known viscosity (water–glycerol mixtures) is used for this purpose.[63] The rotational rate of hemoglobin (the abscissa in Figure 17) is calculated from the Stokes–Einstein equation for a sphere of radius r, tumbling in a medium with viscosity η (Equation 46):

$$\tau_r = \frac{4\pi\eta r^3}{3kT} \qquad (46)$$

Figure 17 Dependence of V_2' diagnostic ratios on the rotational correlation time. The curves are simulated with Equation (63) using the parameter values from Table 1.

Table 1 STESR parameters from maleimide spin label–hemoglobin calibration curves[63]

Parameter	$I_0(H_{res})/I(H^*)$	a (μs)	b (μs)
L''/L	1.88	6.18	67.9
C'/C	1.01	0	21.1
H''/H	2.17	21.7	210

Table 2 Useful constants

Constant	Symbol	Value	Units
Planck's constant	h	6.63×10^{-34}	J s
	$\hbar$	1.06×10^{-34}	J s
Bohr magneton	β	9.27×10^{-24}	$J T^{-1}$
Free electron g factor	g	2.00232	
Electron magnetic moment	μ	-9.29×10^{-21}	$J T^{-1}$
Magnetogyric ratio	γ	$-1.76 \times 10^{+11}$	$s^{-1} T^{-1}$
Boltzmann constant	k	1.38×10^{-23}	$J K^{-1}$

The parameter values listed in Table 1 were obtained for maleimide spin-labeled hemoglobin tumbling in different water–glycerol mixtures. In principle, these values should be transferable from one laboratory to another. In practice, each cavity is sufficiently different in its microwave distribution and modulation fields that separate calibrations are often constructed. New calibrations are also necessary for different spin labels. Changes to the magnetic tensors and relaxation times alter STESR line shapes. In rare cases, full numerical simulation of the V_2' line shape is used to determine the correlation time, but the computational time required is still prohibitive.[68]

Anisotropic Motion. The effective rotational correlation times (τ^{eff}) obtained from such calibration curves reflect rates for isotropic rotation. However, isotropic motion is not very common in biological systems. For example, the nonspherical shape of the diffusing molecules or the restoring potential of the media results in anisotropic motion. Intuitively, rotation about the long axis of a cylinder is faster than the tumbling motion around its short axis. Assigning an isotropic τ_r to an anisotropic motion is obviously in error. For elongated molecules correlation times for rotation about the major and minor axes are given by Equations (47) and (48):

$$\tau_{\parallel} = \frac{f_{\parallel}}{4kT(1 + f_{\parallel}/2f_{\perp})} \tag{47}$$

$$\tau_{\perp} = \frac{f_{\perp}}{6kT} \tag{48}$$

where T is absolute temperature and the frictional coefficients $f_{\parallel}$ and $f_{\perp}$ are a function of the shape of the molecule.[64,65] For a cylinder of length $2a$ and radius b the frictional coefficients are given by Equations (49) and (50):[66]

$$f_{\parallel} = 8\pi\eta ab^2[0.96(1 + \delta_{\parallel})] \tag{49}$$

$$f_{\perp} = \frac{8\pi\eta a^3}{3[\ln(a/b) + \delta_{\perp}]} \tag{50}$$

where $\delta_{\perp}$ and $\delta_{\parallel}$ are as given by Beth and Robinson (Equations 51 and 52):[67]

$$\delta_{\parallel} = 0.688\left(\frac{b}{a}\right) - 0.202\left(\frac{b}{a}\right)^2 \tag{51}$$

$$\delta_{\perp} = -0.661 + 0.891\left(\frac{b}{a}\right) \tag{52}$$

The anisotropic diffusion tensor (D) creates an additional complication. The effect of the molecular rotation on the spectral line shape is a function of the label orientation with respect to the diffusion axis. If the principal axis of diffusion is parallel to the z-axis of the spin label, the motion interconverts the x- and y-components only. If it is parallel to the x-axis, then the y- and z-components will be mixed. To describe fully anisotropic diffusion of the anisotropic tensor, six parameters are needed: three diffusion coefficients about the x-, y- and z- axes and three Eulerian angles describing the orientation of the diffusion tensor with respect to the magnetic tensor.

The problem is simplified if either the diffusion tensor (D) and/or the magnetic tensors (g or A) are axially symmetric: the elements of the diffusion tensor are related to the correlation times by $\tau_{\perp} = 1/(6D_{\perp})$ with a corresponding expression for $\tau_{\parallel}$. It has been shown that the effective correlation time obtained from the L''/L and H''/H line-height ratios of STESR spectra ($m_I = \pm 1$) can be described in terms of $D_{\perp}$, $D_{\parallel}$ and the angle θ between the diffusion and magnetic tensor axis (Equation 53):[68]

$$\tau_R^{\text{eff}}(\pm 1) = \frac{1}{3[D_{\parallel}\sin^2\theta + D_{\perp}(1 + \cos^2\theta)]} \tag{53}$$

When $\theta = 0^{\circ}$ the outer manifolds reflect $D_{\perp}$ which defines the z- and x-(y-) element conversion ($D_{\parallel}$ leaves the nitroxide z-direction unchanged). If $\theta = 90^{\circ}$ the intensity of L'' and H'' is determined by $D_{\parallel}$, which now interconverts the z- and x-, y-axes.

In some cases, anisotropic rotation is about a single axis and the motion can be described by a uniaxial model. The mobility of transmembrane peptides or proteins in lipid membranes is a good example. A uniaxial model, with a single diffusion tensor element $D_{\parallel}$ and an angle θ defining the relative orientation of the magnetic and diffusion axes, is sufficient to simulate STESR spectra of membrane-bound proteins.[69] If θ is not known, then $\tau^{\text{eff}}(\pm 1)$ gives an upper estimate of $0.5\tau_{\parallel}$ ($\theta = 90^{\circ}$). It is important to realize that the changes of the θ angle, brought about by conformational changes, might result in STESR line-shape changes which can be mistakenly interpreted as changes in protein dynamics. A quick diagnostic for the presence of anisotropic motion is the comparison of the effective correlation times estimated from the C'/C ratio and from L''/L (H''/H). If they agree,

then the motion is likely to be isotropic. If they are different, then either the overlap of the nuclear manifolds is different in hemogiobin calibration spectra (unlikely) or the motion is anisotropic.[70] If the change in the STESR spectra is to be interpreted in terms of changed motional rate and not changed anisotropy of motion, then at least the ratio of the correlation times $\tau^{eff}(\pm 1)/\tau^{eff}(0)$ should stay constant.

Another motional model commonly encountered in biology is restricted diffusion. In such a model, the motion is isotropic but constrained in amplitude. The smaller the amplitude of motion, the slower is the apparent mobility derived from isotropic calibration. When the amplitude is $<30°$, the effective correlation time can be a factor of 10 larger than the actual τ_r and for amplitudes $>60°$, τ^{eff} approaches τ_r.[71] For small amplitudes, there is no isotropic line shape which will match the STESR spectrum of restricted motion. The amplitude effect is not just reflected in one or two places in the spectrum, but rather it is distributed across the whole line width.

An extensive review by Beth and Robinson[67] deals with the effects of anisotropic motion on STESR spectra and the theoretical simulations of line shapes. Numerical simulations are based on the transition rate matrix which couples neighboring angular zones with the rate of angular reorientation. The SLE approach and spin density matrix method have also been used. Both approaches have been applied successfully to isotropic and anisotropic motional models. The continuous increase in computational speed bodes well for the routine application of STESR simulations to analyze experimental data.

5.2.1.4 Examples in Muscle Proteins Microsecond motions are common for large macromolecular complexes (1 MDa) such as are present in muscle. The timescales of force generation, the actomyosin ATPase cycle and muscle activation coincide with the micro-to millisecond timescale of STESR, thereby making it the method of choice. The first application of the method established the dynamics of myosin, its subfragments and actin.[72] Thomas et al. showed that the myosin head is capable of moving independently of the large myosin filament. Such motion was a prerequisite for force production. When bound to actin, in the rigor state (no ATP) the myosin heads were immobilized but when ATP was added the heads detached and were free to move.[73,74]

Subsequent studies in muscle fibers at various intermediate states of the acto-myosin ATPase cycle have established a progressive decrease of catalytic domain mobility during the contractile cycle: the 10-μs motion of relaxed and weakly attached heads[75] became 80 μs just before force was generated[76] and was completely "frozen out" in the postpower stroke states of ADP and rigor. In the ADP state the head, although globally rigid, retained "breathing motions", which were suppressed on the release of nucleotide.[77] It is believed that this gradient in protein mobility reflects tighter and more stereospecific binding as myosin progresses through the contractile cycle (Figure 12).

The dynamics of the myosin head are complicated by the fact that this elongated protein does not behave like a rigid body. A comparison of the dynamics of the catalytic and regulatory domains revealed a three-fold difference in the rate of motion for the two domains.[78] Moreover, the two domains were found to have dramatically different orientational distributions.[57] These results highlight the complexity of the conformational changes in the actomyosin system: force generation is not synonymous with force transmission and both events involve changes of dynamics and orientation.

This complex behavior of myosin is in contrast to that of actin. Neither the orientation nor the dynamics of actin monomers, as probed by labels attached near the myosin binding site, were affected by head attachment.[79–82] The absence of any orientational changes in contracting muscle fibers was also observed using spin-labeled toxin phalloidin bound rigidly to the interface between the actin monomers.[83] This agrees with the current model of actin's passive role in force production in providing "tracks" for myosin motor protein to "walk" on.

Force activation involves a complex pathway with subtle changes in protein–protein interactions. It is mediated by the conformations and dynamics of the participating molecules. Smooth muscle is activated via phosphorylation of myosin light chain 2, whereas skeletal muscle is regulated by a thin filament based system involving Ca^{2+} binding to TnC. STESR spectra of phosphorylated myosin with a probe bound to myosin light chain 1 have implied increased motional freedom of the head. This finding supports a model[86] in which unphosphorylated heads are tied to the surface of myosin filaments and inhibited from binding to actin.[87] Phosphorylation abolishes the electrostatic attraction to the filament surface allowing the heads to interact with actin.

In skeletal muscle, binding of Ca^{2+} to TnC initiates a signaling pathway from the thin to thick filament which ultimately activates muscle contraction. Biochemical changes in the affinity of myosin for actin and of TnC for Ca^{2+} have a structural basis that is readily observed by both STESR and conventional ESR. The mobility and orientation of TnC (and TnI) has been found to be similarly affected by the binding of myosin heads to actin or by Ca^{2+} binding to TnC.[84] Interestingly, TnC was capable of sensing not only the binding of the myosin heads to actin but also the intermediate ATPase states.[85]

5.2.1.5 Examples in Membranes Rotational diffusion of membrane-bound proteins is often the best way of

determining the oligomerization state in their native environment without the possible dissociative effect of detergents. STESR of various integral proteins has revealed monomers such as rhodopsin,[88] dimers such as cytochrome oxidase[89] and ADP–ATP carrier[90] or even higher oligomers such as Na, K-ATPase.[91]

The biological significance of dynamic structural changes is best illustrated by the Ca-ATPase,[92] whose molecular dynamics correlate with transport activity.[93,94] As shown by ST-EPR, allosteric interactions between Ca-ATPase polypeptide chains and catalytically important domain interactions involved in the transport cycle are regulated by both alterations in membrane lipid composition, anesthetics, and the regulatory protein phospholamban.[95–97] Thus, physiological regulators of calcium transport modulate catalytically important motions and provide a structural basis for β-adrenergic stimulation in the heart.

Protein dynamics measured by STESR and conventional ESR have differentiated between two models of steroid biosynthesis in mitochondria: the shuttle mechanism and the ternary complex of adrenodoxin, P450 and adrenodoxin reductase. Adrenoxin was found to form binary complexes (but not ternary complexes) with either P450 or adrenodoxin reductase, supporting a shuttle mechanism.[98]

An excellent example of the potential of STESR in describing complex anisotropic motions is in the study of the transmembrane anion transporter Band 3 by Hustedt and Beth.[69] The STESR spectra were simulated using a uniaxial model for protein rotation. The diffusion rate and the angle between the magnetic and diffusion tensor were freely floated in the least-squares fits to experimental spectra. The uniqueness of the solution was corroborated by the orientational study of Band 3 in oriented erythrocytes.[55]

5.2.2 Mobility and Time Domain Methods

The measurement of the molecular dynamics by time-resolved ESR methods is still in its infancy. Specialized hardware is necessary to perform such experiments. Spectral diffusion due to the reorientation of spins can be observed either by recovery from saturation at the resonant field (saturation recovery ESR) or by arrival of saturation originally induced at some other nonresonant field (pulsed ELDOR). The initial promise of these methods was not fulfilled when it was shown that the nuclear relaxation, which couples different nuclear manifolds, contributed significantly to spectral diffusion. Combining pulsed ELDOR and saturation recovery differentiates between nuclear relaxation and rotational spectral diffusion and can be used to measure the true rotational correlation time.[99]

2-D FTESR methods appear to be more promising. Nuclear relaxation is seen as cross peaks between the manifolds and can easily be distinguished from homogeneous broadening and spectral diffusion broadening.[100] In the limits of fast motion, τ_r is obtained directly from the homogeneous line width and is defined by the pure T_2 (similar information is obtained from the spin-echo experiments). For slower motions, mixing time between the pulses is varied (2-D ELDOR) and the dependence of spectral broadening on mixing time is used to determine τ_r. Correlation times in the range $1-30\,\mu s$ have been measured for small peptides tumbling in viscous media.[101]

5.3 Kinetic Experiments

Elucidation of molecular mechanisms involves primarily two approaches: (a) entrapment of reaction intermediates with a subsequent reconstruction of the sequence of events and (b) transient kinetics in which the reactions are synchronized with the observed spectral changes. Each of these approaches have potential problems. In the ''trapping'' approach, the states have to be related to the kinetic intermediates. There are cases in which states trapped with substrate or product analogs are not lying on the kinetic pathway. On the other hand, transient experiments are easier to interpret, but technically more challenging owing to lower signal levels, fast acquisition times and difficulties in spectral assignment. The two approaches should be considered complementary. In an ideal world, ''trapping'' approaches should be used to identify and assign signals collected during transient experiments.

Historically, optical spectroscopy was used for transient kinetics owing to inherently higher sensitivity, but ESR is making substantial inroads.[102] Recent advances in resonator design allow for millisecond resolution on microliter samples in the submillimolar concentration range.[103] The DR developed for this purpose is capable of measuring millisecond kinetics in a single shot on $100\,\mu L$ of a $40\,\mu M$ sample with an 8-ms deadtime.[104] The further development of this DR/stop-flow configuration allows the recording of a full spectrum within 100 ms.[105]

Transient ESR was used to resolve the stages of channel formation in lipid membranes. Phospholipid vesicles and membrane channel collicin were mixed rapidly and the time course of the protein absorption to the membrane surface was clearly resolved from the insertion of the channel into the membrane.[106] For collicin the process was fairly slow, with a timescale of seconds, but the formation of another channel annexin was followed on the millisecond timescale.[107] The millisecond time resolution makes ESR a viable

alternative to optical methods in investigations of kinetic processes.

The photolysis of caged compounds, cATP and cCa^{2+}, to study conformational transients has been used primarily in the muscle field and in the study of Ca^{2+}-ATPase. A single ultraviolet (UV) pulse (10 ns in duration with an energy flux of 150 mJ cm^{-2} at 351 nm) from an excimer laser is capable of liberating 0.5 mM ATP (Figure 18a and b). The magnetic field is locked into a position where the initial and final states display a large spectral difference and the intensity at that position is followed in time. In myosin, the pre- and post-ATP hydrolysis states have different mobilities at a labeled residue near the catalytic site, with correlation times of $\tau_r > 100$ ns and $\tau_r \approx 80$ ns. This mobility difference and the associated line-shape difference was utilized in measuring the rate of transition between the two states ($43\,s^{-1}$) and was found to correspond to the hydrolysis rate of ATP[108] (Figure 18a and b). Similar experiments in muscle fibers, measuring both the orientation and the mobility, established that the rapid disorder of myosin heads follows nucleotide binding but precedes hydrolysis. These experiments also determined that the rate of hydrolysis is the same in fibers as in solution.[102]

Transient ESR of the Ca^{2+}-ATPase following cATP photolysis revealed local domain changes around the labeled site which correlate well with the formation of the phosphoenzyme intermediate.[109] A larger and more motionally restricted label was also used to observe global changes, e.g. shape or oligomerization state. No such changes were observed by transient STESR during the ATPase cycle.[110]

Biological photocycles encountered in rhodopsin and bacteriorhodopsin are special cases of cycles that are easily synchronized. The photoisomerization of retinal in bacteriorhodopsin initiates a series of proton transfer reactions via short-lived intermediates culminating in the loss of H^+ at the extracellular surface. Some 50 μs after photoactivation, an intermediate M decays to N when Asp96 transfers a proton to the Schiff base. During the decay of the N state, Asp96 regains a proton from the cytoplasmic site and bacteriorhodopsin reverts to the ground state, thereby completing the cycle. Labels have been attached to a number of cytoplasmic, interhelical and extracellular loops in the vicinity of Asp96 and their mobility was followed after irradiation with light.[111–113] Cytoplasmic sites and those near Asp96 all showed significant changes which coincided with the decay of the M state and recovered with the decay of the N state.[112] The efforts of Hubbell's and Steinhoff's groups to describe the molecular mechanism of rhodopsin and bacteriorhodopsin are an excellent example of the power of ESR methods to evaluate both static and transient molecular structures. In summary, the combination of high sensitivity, short mixing deadtimes, and temporal resolution makes ESR an increasingly popular method to study transient kinetics.

Figure 18 (a) Transient ESR of myosin head labeled with iodoacetamide spin label after the photolysis of cATP and (b) expanded transient.[108] (Reprinted with permission from E.M. Ostap, H.D. White, D.D. Thomas, *Biochemistry*, **32**, 6712–6720 (1993). Copyright 1993 American Chemical Society.)

5.4 Protein Folding

In the last few years, site-specific spin labeling has been applied to protein folding problems.[114,115] The advantage of the ESR approach to protein folding lies in site specificity as the denaturation of local domains can be followed independently of global denaturation. This approach relies on differences in the mobility of spin labels in folded and denatured proteins. The folded protein provides steric restrictions due to secondary structure and tertiary contacts whereas the denatured one does not. The ESR spectra for the denatured fraction are a composite of sharp, motionally averaged line shapes in contrast to broader, immobilized spectra observed for the folded protein. Fractions of protein in each form are easily calculated by spectral subtractions and by line shape integrations.[115] Cooperativity and stability of the given region are determined from spectral titration with a denaturing agent, e.g. GdnCl, urea or heat. Differences in the melting of hydrophobic and aqueous surfaces of the β-strand pore of FepA receptor were observed by cysteine scanning of the polypeptide chain lining the channel. The hydrophilic surface was more stable and cooperative in the transmembrane portion of the strand than the

extramembraneous strand ends. The residues exposed to the lipid exhibited noncooperative melting and did not denature completely even at the highest concentrations of denaturants.[116]

ESR is also capable of sensing multiphasic folding intermediates. Carbonic anhydrase was found to denature via an intermediate characterized by a compact and stable molecular core with a more dynamic periphery.[117] In the presence of the chaperonin GroEL, the intermediate core was destabilized and partially melted, explaining how GroEL allows for the refolding of misfolded proteins.[118] The development of new resonators, as mentioned previously, has facilitated detailed analysis of folding kinetics. The initial phases (<20 ms), ascribed to helix formation, were recently resolved by stop-flow ESR.[104]

5.5 Ligand Binding

Two less well known applications of spin labeling are the determination of the binding of small ligands and the aggregation of large (the latter reviewed in section 5.7.4). The binding of small ligands is followed by changes in their mobility. Spin label analogs of ligands have sharp, motionally narrowed spectra when free in solution. Binding to a larger target slows the motion of the label and the spectra become broadened. Spectral resolution between the broad/bound species and the narrow/free ligands allows quantification of bound species and hence calculation of binding isotherms. The binding of mellitin to α-crystallin[119] and the binding of nucleotide analogs to ATPases were determined by this method. Binding studies are not limited to ligands carrying a spin label. Competition of unlabeled and labeled analogs is used to determine the K_d of unlabeled ligands. The binding of ATP, ADP, adenosine thiotriphosphate (ATPγS), adenosine imidotriphosphate (AMPPNP) and adenosine methylenetriphosphate (AMPPCP) to myosin was determined by the displacement of spin-labeled ATP.[120]

A good example of ESR applications in ligand binding is the association of lipid spin labels with intrinsic membrane proteins. The differences in mobility are small and the spectra of bound and free labels are not resolved. Small broadening due to exchange between free and restricted environment was simulated to extract the equilibrium constant and the number of binding sites.[61]

Finally, the binding of metals to proteins can be established by ESR. Mn(II) has a characteristic six-line spectrum when free in solution, but no signal when bound to protein. The decrease of free Mn(II) signal upon addition of a protein identifies the fraction of bound metal.[121] As shown in the example with ATP analogs, displacement of bound Mn(II) by other metals can be used to determine their binding affinity.

5.6 Distance Measurements

ESR is capable of measuring short distances (2–25 Å) between selected sites. The method relies on the distance-dependent interactions between two spin labels (spin label–spin label method), or an interaction between a spin label and a paramagnetic metal (spin label–spin probe method). The physical basis for the coupling between the two spins is the exchange interaction (J) arising from the overlap of the orbitals of unpaired electrons and the dipolar interaction between magnetic moments of the two spin labels. The spin label–spin probe method relies on the enhancement of the relaxation of the spin labels by paramagnetic metals which have considerably faster relaxation rates and provide an efficient relaxation pathway for nitroxides.

5.6.1 Spin Label–Spin Label Method

5.6.1.1 Exchange Interaction, Distances <8 Å At distances shorter than 8 Å, the σ- or π-orbitals of the neighboring unpaired electrons can overlap, creating a single spin state: singlet (spins are antiparallel) or triplet (spins are parallel) state. Unlike nuclear spin, electron spin coupling propagates both through space and through covalent bonds. Through-bond coupling drops off very quickly and is insignificant at a distance greater than a few bonds. The through-space coupling strength (J) is a function of the interspin distance r_{dd} (Equation 54). J diminishes exponentially, with a 1-Å interaction distance from the initial value of $J_0 = 300$ G. In the strong exchange regime, when J is much larger than hyperfine interactions, the combined nuclear spin is 2 and the spectrum displays a five-line pattern. For weak coupling ($J < A_0$), the interaction asymmetrically broadens the low- and high-field resonances. The shift of the downfield edge of the low-field resonance in the presence of the second label (ΔH_{dd}) is proportional to J and hence to the interspin distance.

$$\Delta H_{dd} \approx J = J_0 \exp(-\beta r_{dd}) \tag{54}$$

For example, a 0.1-Gauss broadening implies an interspin distance of ~8 Å, defining the upper limit of the sensitivity.

Spin exchange in peptides labeled with two probes has been used to determine helical folds.[122] Some proteins contain 3_{10}-helices between β-strands or at the end of α-helices and their detection in solution is difficult. Fiori and Millhauser utilized a difference of distance between the i and $i+4$ residues along the α- and 3_{10}-helices to distinguish between the two helical forms. The i to $i+3$ distances are similar in both helices (6–8 Å), but the i to $i+4$ distance for the 3_{10}-helix is outside the range of the exchange interaction (10–16 Å) and within the

range for an α-helix (7–11 Å). Placing pairs of labels in the i, $i+3$ and $i+4$ positions along the synthetic helices identified the predominantly α-helical regions in the N-terminus (equal broadening of i, $i+3$ and i, $i+4$ pairs) with the 3_{10}-helix at the C-end (no broadening of the i, $i+4$ pair). A comparison of 16- and 21-residue peptides revealed a length-dependent equilibrium between the α- and 3_{10}-helices. Shorter peptides favored the 3_{10}-helix whereas the longer peptides favored the α-helix.

Transition between the two helical forms might provide a mechanical pathway for allosteric mechanisms. The α-helix has more residues per turn and is significantly shorter, hence the 3_{10}-helix to α-helix transition will mechanically pull on the neighboring domains.

5.6.1.2 Dipolar Coupling Distances: 8–25 Å In addition to the exchange interaction, neighboring spins experience local fields induced by their respective magnetic dipoles. The local fields can add to or subtract from the external field splitting each of the resonances. This dipolar interaction has an r_{dd}^{-3} dependence which results in discernible line-shape changes for distances up to 25 Å. The contribution of the exchange interaction for distances over 10 Å is negligible.

The strength of the dipolar interaction is a function of eight parameters: the interspin distance r_{dd}, the angle between the static magnetic field and the interspin vector and the six angles describing the orientation of each of the spin labels with respect to the interspin vector. Protein dynamics also affects these parameters on the timescale of the experiment: the global motion of the molecule modulates the angle with respect to the field, intradomain motions modulate the interspin distance and the interspin angles. The full solution of dipolar ESR line shapes in the presence of motion poses a formidable challenge.

The geometry of the NAD coenzyme bound to glyceraldehyde dehydrogenase (GAPDH) is the best example of the approaches taken to tackle this problem. Since GAPDH is a tetramer it can bind four molecules of coenzyme NAD. The relative orientation of the coenzyme was determined from the dipolar splitting of a spin label analog of NAD. Hustedt et al. used different microwave frequencies (9, 35 and 94 GHz) coupled with sophisticated fitting procedures to solve independently for most of the parameters listed above.[123] The ESR structure was consistent with the geometry derived from molecular modeling using a crystal structure of the apo-enzyme.

Another example is the open form of α-helices in protic solvents.[124] Alanine-rich peptides, incorporating the unnatural spin-labeled amino acid TOAC (2,2,6,6-Tetramethylpiperidine-1-oxyl-4-amino-4-carboxylic acid), showed a strong dipolar interaction for the i, $i+4$ labeled peptides with less interaction between the i, $i+3$ sites. Molecular modeling revealed a shorter interspin distance and larger backbone torsional angles, consistent with 3.8–3.9 residues per turn compared with 3.6 residues for a standard α-helix. The open configuration allows for the formation of additional hydrogen bonds with amide carbonyls while preserving helical hydrogen bonds. ESR proves to be an important tool in identifying subtle changes in helical folds induced by the local environment.

Short of solving the general case as above, two simpler cases are often encountered: (1) the static dipolar case in which all motions are frozen out, the labels are disordered on the surface of the protein and the protein itself is isotropically disordered in the magnetic field, and (2) the motionally averaged case in which the anisotropy of the dipolar interactions is averaged ($\tau_r < 6$ ns) and the spectrum is homogeneously broadened by spin–spin interactions.

In the first case, the nitroxides and the sample are rigid and each of the resonance peaks are broadened by the Pake function given in Equation (55):

$$\Delta H_{dd} = \pm \frac{3g\beta(3\cos^2\theta - 1)}{4r^3} \tag{55}$$

where θ is the angle of the interspin vector in the magnetic field.

Convolution of the resonances with the Pake pattern yields a characteristic line shape with dipolar wings in the low- and high-field regions of the spectra. The Pake function is obtained from the spectrum by a Fourier transform,[125] line shape fitting[126] or by empirical calibrations.[38] Empirical calibrations relate the line heights of the low- and high-field resonances to the line height of the central peak (Equation 56):

$$r_{dd} = 9.3 + \frac{0.77}{(d_1/d) + 0.36A_{zz} - 1.76} \tag{56}$$

where r_{dd} is in ångstroms and A_{zz} is in gauss, d is the line height of central resonance, and d_1 is the difference between low-field peak and high-field trough.

Alternatively, the Van Vleck relation between the second moment of the central resonance M_2 and r_{dd} is used in obtaining the distance (Equation 57):

$$M_2 = \frac{3}{20}\frac{g^2\beta^2}{r_{dd}^6} \tag{57}$$

where r_{dd} is in ångstroms. The second moment is given by the Gaussian part of the peak-to-peak line width (Equation 58):

$$M_2 = \left(\frac{\Delta H_{pp}^G}{2}\right)^2 \tag{58}$$

The Pake broadening approach was verified for interspin distances of doubly labeled rigid synthetic polypeptides in which distances in the range 8–24 Å were predicted from the structure.[125] The method was also verified for larger molecules by comparison with an X-ray determined structure of spin-labeled insulin. The interspin distances in a crystal were in excellent agreement with those found in solution by ESR. Distribution of distances due to protein flexibility in solution was found to be twice as large in solution as in the crystal.[126] It is important to note that ESR is one of the very few techniques which can estimate conformational heterogeneity of a protein in solution.

Static dipolar broadening is rapidly gaining popularity. It was used in the analysis of helix packing of lactose permease in the membrane.[127] Spin labels placed on surfaces which faced each other displayed dipolar broadening. Analysis of the extent of broadening as the label is moved around the helix identified the relative rotation of neighboring helices. Dipolar broadening was also used in the elucidation of the opening/closure of K-channels[128] as described in detail in section 5.7.4.

The static dipolar approach (case 1) fails when the proteins are not rigid on the nanosecond timescale of an ESR experiment. If the spin mobility is high enough to modulate the anisotropy of dipolar interactions (Equation 59)

$$\tau_r \leq \left(\frac{g\beta\Delta H_{dd}}{h}\right)^{-1} = \left(\frac{3\pi g^2\beta^2}{r_{dd}^3 h}\right)^{-1} \qquad (59)$$

the rotational modulation of the interspin vector results in the broadening related to both the distance and the correlation time (Equation 60):

$$\Delta H_{dd} = \frac{3}{10}\frac{\gamma^4}{g\beta}\hbar^3\frac{\tau_r}{r_{dd}^6}\left(3 + \frac{5}{1+\nu^2\tau_r^2} + \frac{2}{1+4\nu^2\tau_r^2}\right. \qquad (60)$$

Line-shape comparisons of singly and doubly labeled samples reveal the extent of dipolar broadening from which the r_{dd} distance is calculated assuming (or measuring) an appropriate correlation time for the molecule. McHaourab et al.[129] tested this approach on a series of labeled sites in T4 lysozyme (8 Å < r_{dd} < 23 Å) and found them to be in excellent agreement with the structure of the protein (Figure 19a and b). Note that the motional modulation regime is a function of both the interspin distance and the rotational correlation time, e.g. dipolar interactions of labels 15 Å apart are averaged for motions with correlation times of ≤6 ns.

The above examples illustrate the static and motionally averaged cases of spin–spin interactions. However, often the precise mechanism of spin–spin interactions is not known as there are contributions from static dipolar interactions, from the rotational modulation of the interspin vector and from the modulation of the interspin distance. Although there is currently no theory fully describing the changes in the ESR line shape, the presence of line-width broadening is always indicative of two labels being in the range 10–20 Å from each other. Even the simplest, qualitative statement of spin–spin distance can yield important structural information. The presence of spin–spin interactions has helped to elucidate changes in the topology of the cytoplasmic portion of rhodopsin following light activation. It has explained how rhodopsin initiates the phosphorylation cascade by rhodopsin kinase.[130]

Figure 19 (a) An ESR spectrum broadened by the presence of another nitroxide and (b) the line width as a function of the interspin distance.[129] (Reproduced with permission from H.S. McHaourab, K.J. Oh, C.J. Fang, W.L. Hubbell, *Biochemistry*, **36**, 307–316 (1997).)

Interested readers are directed to an excellent review by Hustedt and Beth.[47]

5.6.1.3 Very Long Distances: >25 Å The upper limit of 25 Å for the detection of dipolar interactions is defined by an observable broadening: ~3 G for inhomogenously

broadened samples of rigid samples and 0.2 G for the sharp, motionally narrowed line shapes. This limit can be extended by time-resolved techniques, which unlike the continuous-wave methods do not rely on line broadening. A variety of pulsed ESR methods have been developed for this purpose. Double electron–electron resonance (DEER) is one method in which the spin echo is observed as a function of time of an intervening pulse applied at a second frequency,[131,132] or at the same frequency as in "2 + 1" resonance.[133] In both cases, an amplitude of the spin echo is modulated by Pake dipolar interactions which are extracted by Fourier transformation of the echo modulation. In model compounds, the distances recovered by DEER ranged between 20 and 33 Å,[132] whereas the "2 + 1" scheme elucidated an interspin distance of 35 Å between nitroxides attached to β-93 cysteine in tetrameric hemoglobin.[133] Double quantum 2-D FTESR is the most recent technique that looks directly at spin–spin interactions i.e. the filtering out of a "normal" ESR spectrum originating from isolated spins. This method has been tested on solid polyproline peptides with an interspin distance of 18 Å.[101]

5.6.2 Spin Label–Paramagnetic Metal Method

An entirely different way of determining distances is by coupling an unpaired spin of a nitroxide radical to a fast-relaxing spin of a paramagnetic metal, e.g. Cu(II) or Fe(III). The spin–lattice relaxation times of many metals are three orders of magnitude faster than those of nitroxide spin labels and thus, when coupled to nitroxides, they provide an efficient relaxation path. The relaxation enhancement can be detected by either increased Lorentzian broadening or directly by the shortening of T_2 or T_1 of the spin label in the presence of the metal (Equation 61):

$$\Delta\left(\frac{1}{T_{1s}}\right) = \frac{\mu^2\gamma^2}{6r^6T_{1f}}\left[\frac{4}{5(w_1-w_2)^2}+\frac{24}{5(w_1+w_2)^2}+\frac{12}{5w_1^2}\right] \quad (61)$$

All three methods have been tested in spin labeled hemoglobin in which a nitroxide at residue 93 of the β-chain was coupled to Fe(III) bound to the heme. The distance of 15 Å between the label and iron was in excellent agreement with molecular modeling.[134]

The metal relaxation is not limited to naturally occurring metal binding sites. Site-specific spin labeling has recently been extended to the engineering of metal binding sites.

Voss et al. engineered Cu(II) binding sites to T4 lysozyme and lactose permease by introducing histidine residues in consecutive turns of the α-helix.[135,136] Spin labels were placed between 8 and 18 Å away from the metal site by cysteine mutagenesis. The ESR line shapes were broadened by paramagnetic Cu(II) chelated by the histidine residues. Binding of diamagnetic metals did not affect the line shape. The spectra were analyzed in terms of the dipolar model of Leigh,[137] which relates line-shape broadening to the interspin distances r_{dd} and metal relaxation time T_{1m} (Equation 62):

$$\Delta H_{dd} = \frac{g\beta\mu^2 T_{1m}}{\hbar r^6}(1-3\cos^2\theta)^2 \quad (62)$$

where μ is the magnetic moment of the metal.

A convenient experimental parameter is the amplitude of the central line. The amplitude decreases with decreasing spin–spin separation. Calibration curves derived from computer simulations were used to estimate the interspin distances in two model systems, lactose permease and T4 lysozyme. Excellent agreement was found, not only for the rigid samples for which Leigh's model was originally developed, but also for motionally narrowed spectra due to the mobility of the nitroxides with respect to the protein. For Leigh's model to hold, the interspin vector must not move on the same timescale as dipolar interactions, which is T_1 of the metal. This is satisfied for molecules larger than 15 kDa ($\tau_r > 6$ ns) and for metals such as Cu(II) where T_1 is 1–3 ns. The distances obtained for T4 lysozyme in solution at room temperature were approximately 1 Å shorter than those obtained from frozen proteins.[136] This small underestimation of the distance is compensated by the biological advantage of performing experiments at room temperature and by the increased fidelity in measurements of small-amplitude changes in sharper, motionally narrowed spectra. Another elegant application of this method involved the determination of helix packing in lactose permease. Interspin distances between three helices labeled with nitroxide labels and a metal site containing Cu(II) determined the relative orientation of the helices and their relative tilt.[138]

Currently this method is limited to distances between 10 and 20 Å for Cu(II) with the X-band. Inspection of Leigh's Equation (61) suggests that the distance range might be extended to ~50 Å by using lower ESR frequencies (S-band), metals with a larger magnetic moment (Gd^{3+}) or shorter T_1 (Ni^{2+}) and also by direct measurement of relaxation times.[139]

5.6.3 Collision Exchange

A variation of spin–spin interactions is the relaxation of spin labels by collisions with soluble paramagnetic agents such as metals or O_2. Collisions lead to the HSE, enhancing spin–lattice relaxation according to Equation (63):

$$\Delta T_1^{-1} = kW_x \quad (63)$$

Figure 20 Power saturation of two samples with different $P_{1/2}$ values.

where k is a factor accounting for the efficiency of collisions and statistics of diffusion in two or three dimensions and W_x is the bimolecular collision frequency. The collision frequency is of interest because it reflects the accessibility of the labeled site to the relaxant. Comparison of W_x for various sites reveals which residues are exposed or hidden and their secondary structure content and identifies tertiary interactions.

Relaxation enhancement is measured directly by pulse methods (saturation recovery or spin echo ESR) or by continuous-wave power saturation. The amplitude of the ESR signal increases linearly with the microwave magnetic field ($H_1 \propto P^{1/2}$) until the Boltzmann equilibrium population difference is perturbed and the signal between excited and ground states decreases. Samples with a long T_1 saturate easily and addition of relaxing agents relieves this saturation (Figure 20).

The peak-to-peak amplitude (A) of the first-derivative spectrum is given by Equation (64):[140]

$$A = \frac{A_0\sqrt{P}}{1 + \left(\sqrt[\varepsilon]{2} - 1\right)(P/P_{1/2})^{\varepsilon}} \tag{64}$$

where ε depends on the resonance line shape and varies between 0.5 for purely Lorentzian and 1.5 for Gaussian line shapes; A_0 is an instrument scaling factor and $P_{1/2}$ is the half-saturation power (the power at which the signal is half of what it would be in the absence of saturation). $P_{1/2}$ is determined either graphically or by the fitting of experimental curves to Equation (64). The $P_{1/2}$ value is then used in calculating T_1 according to Equation (65):

$$T_1 = \frac{2^{2/3} - 1}{\gamma^2 \Lambda^2 P_{1/2} T_2} \tag{65}$$

where Λ is an instrumental factor which depends on the power-to-magnetic field conversion of the resonator. Since T_2 for nitroxides is 2–3 orders of magnitude smaller than T_1 and because T_2 is proportional to the peak-to-peak line width of the central line ($T_2 \propto 1/\Delta H_0$), the collision frequency is determined from Equations (63) and (65) (Equation 66):

$$W_x \propto \Delta P_{1/2} T_2 = \frac{\Delta P_{1/2}}{\Delta H_0} \tag{66}$$

In order to account for differences in resonators and spectrometers between various laboratories, a dimensionless accessibility parameter π was defined; π normalizes W_x to the half-saturation power and line width of a diphenylpicrylhydrazyl (DPPH) standard.[141] (Equation 67):

$$\pi = \frac{\Delta P_{1/2}}{\Delta H_0} \frac{\Delta H_0^{\mathrm{DPPH}}}{P_{1/2}^{\mathrm{DPPH}}} \tag{67}$$

Trends in accessibility to various relaxing agents are used to determine the local environment of spin labels. The relaxants can be nonpolar such as O_2 partitioning into lipid bilayers, or polar with preference for the aqueous phase. The latter includes neutral relaxants such as NiAA [nickel(II) acetylacetonate] and NiEDDA [nickel(II) ethylenediaminediacetate] and charged relaxants such as CROX [potassium tris(oxalatochromate)].[142]

An important application of collisional relaxation is the determination of the secondary structure of peptides and proteins. Patterns of collisional accessibility along the polypeptide chain can reveal α-helical folds, β-sheet strands, immersion in membranes and chain tilt within the membranes. These applications are described at length in section 5.7.2.

5.7 Structural Biology

The advent of site-specific spin labeling established ESR as a structural technique.[41–43,46,142] In the first study,[30] comparison of the relaxations enhancement of four labeled cysteine mutants of bacteriorhodopsin identified membrane embedded and surface exposed residues. Since then, these approaches have been refined and extended to establish (a) the topology of membrane bound proteins, (b) the secondary structure of proteins by cysteine scanning and following trends in accessibility and mobility of residues and (c) the tertiary folding of proteins by distance measurements between engineered sites. Most of the examples discussed below are from work of Hubbell et al.

5.7.1 *Side-chain Environment – Immersion in Membranes*

Differential effects of nonpolar (O_2) and polar (NiAA, CROX) relaxants are used to measure the immersion depth of membrane proteins. This technique relies on opposite concentration gradients for polar and nonpolar relaxants within lipid membranes. The concentration of nonpolar reagents increases with the immersion depth and the concentration of polar reagents decreases. The further the nitroxide is from the aqueous interface, the stronger is the relaxation enhancement by nonpolar reagents and the weaker is the effect of polar relaxants. The difference (Φ) between the polar and nonpolar reagents as defined in Equation (68) is thus a function of the immersion depth:[140]

$$\Phi = \ln \frac{\Delta P_{1/2}^{\text{nonpolar}}}{\Delta P_{1/2}^{\text{polar}}} \tag{68}$$

Calibration curves of Φ are constructed using lipid spin labels with nitroxides at defined positions along the acyl chains and these curves are used to determine the immersion depth of labels attached to membrane-bound proteins (Figure 21a and b).

This relatively simple method, when used in conjunction with cysteine scanning, differentiates between membrane-bound and solvent-accessible surfaces of membrane-associated proteins or peptides. As the nitroxide is moved along the length of a polypeptide chain, $\Delta P_{1/2}$ for the polar agent shows minima and maxima for the residues interacting with the lipid bilayer and the surface-exposed residues, respectively. The nonpolar agent has a similar pattern of minima and maxima, but it is offset by 180° with respect to the polar relaxant, i.e. maximum relaxation will be observed for the residues interacting with the membrane and minimum relaxation for water-exposed residues. A similar phase shift is observed for the residues of helices lining the aqueous pores of channels. Residues facing the lumen of the pore show maximum relaxation enhancement for polar agents (minima for the nonpolar oxygen), while the residues facing the membrane environment have maxima for oxygen and minima for CROX, NiAA and NiEDDA.

Such is the case for the ferric enterobactin receptor FepA, the transmembrane β-strand of which was found to line an aqueous channel. The maxima of accessibility to NiEDDA was alternating with maxima to O_2, identifying the β-strand face as lining the channel and the side of the β-strand facing the lipid bilayer.[143] Similar results have identified residues lining the aqueous channels in collicin,[144] diphtheria toxin[145] and annexin.[107]

Figure 21 Immersion of a polypeptide chain in the lipid bilayer. Differential accessibility to polar ( ) and nonpolar (●) relaxants, Φ, identifies the distance from the aqueous surface. Calibration curves of Φ are constructed using lipid spin labels with nitroxides at defined positions along the acyl chains.[143] (Reproduced with permission from C.S. Klug, W. Su, J.B. Feix, *Biochemistry*, **36**, 13027–13033 (1997).)

5.7.2 *Secondary Structure Determination*

Cysteine scanning also allows for secondary structure determination. One method, based on the exchange interactions between nitroxides attached to the i, $i+3$ and i, $i+4$ residues, identifies α- and 3_{10}-helices and was discussed in section 5.5.1.1. Other methods rely on changes in nitroxide mobility and accessibility to relaxing agents. The periodicity of steric interactions varies along the polypeptide chain, which in turn determines the nitroxide mobility and/or periodicity of relaxation effects.[146] For example, an α-helix in an unevenly

Figure 22 Patterns of solvent accessibility for (a) β-strands of α-hemolysin (two-residue periodicity) and (b) an α-helix of *Streptomyces* K^+ channel (3.6-residue periodicity). The Fourier transform identifying angular periodicity characteristic of α-helix and β-strands is illustrated. (Courtesy of E. Perozo, unpublished.)

solvated environment (owing to the interaction with a membrane surface or another polypeptide chain) shows a pattern of flexibility and solvent accessibility with a 3.6-residue periodicity. β-Strands, on the other hand, will display a two-residue periodicity (Figure 22a and b).

This characteristic periodicity of 3.6 residues was observed for a number of helices of transmembrane proteins: rhodopsin,[146–149] collicin,[143] K-channel[32] and the soluble protein T4 lysozyme.[31] Periodicity of β-strands was observed for the transmembrane protein FepA receptor[143] and water-soluble α-crystallin.[150,151] In some cases ESR has extended the structural information obtained by other methods, for example interhelical loops in rhodopsin.[147] However, in other cases, the secondary structure determined by ESR was the only available source for example FepA receptor[143] and α-crystallin.[150]

An interesting use of SDSL ESR is to extend monomeric (subunit) structures determined by NMR and X-ray crystallography to the structures of functioning macromolecular complexes. The monomeric structure of the soluble (nonfunctional) form of the membrane pore annexin has been solved by X-ray crystallography. A mobility and accessibility profile of 26 single cysteine mutants in the helix–loop–helix motif has revealed a dramatic structural transition when annexin is inserted into the membrane to form a continuous, transmembrane α-helix. As was expected for a membrane pore made of the annexin trimer, one side of the helix was found to be highly solvated.[152]

5.7.3 Tertiary Structure: Conformational Changes

The greatest potential for the above methodologies is the determination of tertiary structure. The current rate of structure determination by X-ray crystallography or NMR (~1000 per year) is too slow to solve for all 120 000 gene products. Fortunately, most proteins are built from well defined, common structural motifs, but are packed in different ways to give proteins their unique three-dimensional structure. It seems that instead of solving ab initio the atomic structure of each protein it will be simpler to determine the relative arrangement of common structural motifs. For instance,

a few chosen mutations can quickly establish whether given helices or β-strands are in a parallel or antiparallel arrangement.[143,153]

Qualitative information about tertiary structure is obtained from mobility and solvent accessibility values, both of which are limited to sites of tertiary contacts, e.g. π (O_2) values are 0–0.05 for buried sites and 0.3 for solvent-accessible surface sites.[119] Additionally, in-phase tracking of accessibility to polar and nonpolar reagents and tracking of mobility patterns identifies surface residues and residues buried within a protein core. The surfaces involved in helix packing in rhodopsin[147,148] and collicin[144] and β-strand packing in α-crystallin[151] have been identified by this in-phase behavior.

The tilt angle of polypeptide chains within lipid membranes is easily determined from the immersion depth of selected residues (see section 5.7.1). The immersion depth is calculated from the Φ parameter (ratio of nonpolar to polar accessibility), which is calibrated in terms of the distance from the membrane surface of lipid spin labels at defined positions. The average depth (d) of consecutive residues is compared with the distance along the chain (d_0). The tilt of the chain with respect to the bilayer normal is given by Equation (69):

$$\alpha = \cos^{-1}\left(\frac{d}{d_0}\right) \tag{69}$$

For β-barrels, the tilt information, combined with number of β-strands, can be used to estimate the diameter of the barrel.[144]

Most of the examples identifying conformational changes are from membrane-bound proteins. In rhodopsin, helices flanking the ionone ring of retinal have been labeled with nitroxides and the interspin distance tracked upon photoisomerization of the retinal.[130,154] The observed rigid body rotation, with an associated change of the tilt angle in one of the flanking helices, resulted in increased accessibility of the cytoplasmic loop. Increased exposure of the loop facilitates binding of transducin to rhodopsin, which is the first step in the phosphorylation cascade of signal transduction pathway.

Conformational changes accompanying insertion into a membrane and pore formation were observed by ESR for the small cytosolic protein annexin. A water-soluble monomer with a helix–loop–helix motif was rebuilt to form a continuous transmembrane helix in the presence of Ca^{2+}. The formation of long helix induced membrane insertion of annexin.[107] In another example, smaller conformational changes were observed by varying the lipid environment of transmembrane proteins. Reconstitution of lactose permease into proteoliposomes induced a small 2-Å movement of neighboring helices.[127]

A particularly rewarding example is that of conformational changes in T4 lysozyme: two structures solved by X-ray crystallography implied a hinge movement which opened the active site by 8 Å. Using strategically placed cysteines near the active site, this predicted opening of the active site was verified in solution.[129] In addition to corroborating the presence of the two conformers, ESR was able to measure an equilibrium of closed and open structures, yielding a unique estimate of activation energy associated with catalysis.

The most spectacular application of ESR to the tertiary/quaternary structure of proteins was that of the bacterial potassium channel by Perozo.[32,128] Nearly a third of the entire protein including two transmembrane helices and the interhelical region flanking a selectivity filter have been scanned with spin labels. This is a total of 62 mutants for the 160 amino acid polypeptide chain. The channel is formed by the tetrameric assembly of the two helices, with one helix (TM2) forming an aqueous pore and the other helix (TM1) located on the periphery. The structure has been solved independently by X-ray crystallography[156] and by ESR from accessibility and mobility profiles.[32] The ESR protein structure determination was further extended to the structural description of the channel opening. The channel is activated by lowering the pH. Sequence profiles of mobility and interspin distances were compared for the open and closed forms, revealing a physical opening of the central pore. The open form was brought upon by a rigid body rotation and tilting of the TM2 helices with an accompanying movement of the peripheral TM1 helices.[128]

5.7.4 Assembly of Polypeptide Chains: Quaternary Structure

Differences in mobility between monomers and oligomers can be used to identify the oligomerization state of proteins. For small proteins, ESR line shapes are motionally narrowed, whereas the spectra of aggregates are considerably broader. Spectral resolution of monomeric and oligomeric forms in a composite spectrum allows for the determination of their respective concentrations in solution and hence thermodynamic parameters of oligomer formation. Oligomerization in a variety of solvents of cecropin AD, a small ion channel, was studied in this way.[157]

The kinetics of the formation of amyloid plaques were monitored by the disappearance of the sharp central line of the spin-labeled amyloid protein monomer.[158] Monomers were found to aggregate initially into an amorphous plaque precursor in which the protein was in equilibrium between soluble monomers and the aggregated protein. The precursor was an initiation site for fibril formation of which the amyloid

plaques are subsequently formed. Characterization of various assemblies and the equilibria between monomers and aggregates are of direct interest in understanding the molecular basis for diseases such as Creutzfeldt–Jacob (''mad cow disease'') and Alzheimer's disease.

An alternative way of following the formation of aggregates is to utilize spin–spin interactions. Interacting monomers lead to a broadening of the ESR spectra, provided that the labels are within the range of spin exchange or dipolar interactions. Spin-labeled insulin B chain was found to aggregate on reduction of the interchain disulfide bonds, but the presence of α-crystallin was found to prevent aggregation. In the absence of crystallin, the spectra of B insulin displayed a broad Lorentzian pattern, characteristic of closely placed spins. This turned into a normal powder pattern upon binding to crystallin.[119]

Titration of spin–spin interactions with unlabeled proteins can be used to estimate the number of monomers forming an oligomer. As the concentration of unlabeled monomers increases, the probability of spin–spin interactions decreases and dipolar broadening is relieved leading to an increase in signal amplitude. For small oligomers, dilution with small amounts of unlabeled protein results in a greater increase of signal amplitude than for larger oligomers. The titration follows a binomial expansion and has been used to establish that the membrane-bound form of annexin is a trimer.[107]

This qualitative approach has been used for annexin pores. While the crystal structure of the soluble form of annexin suggested a hexameric assembly, nothing was known about annexin in membranes. Among the possibilities were a trimeric ring and a hexamer consisting of stacked trimers. To distinguish between these alternatives, cysteines were introduced at the interface between the monomers forming a trimer and on the interface between the trimers forming a putative hexamer. In the soluble form, no dipolar interactions between any of the sites were observed, consistent with the monomeric form in solution. Addition of Ca^{2+}, which triggers membrane binding, resulted in the broadening of the spectra within the trimer but not between the trimers, proving that a trimer and not a hexamer was forming the pore.[107]

6 CONCLUSION

ESR of protein is currently enjoying a renaissance of sorts. In addition to its contributions in studies of protein dynamics and orientation, ESR is being increasingly used as a structural technique. The advances of molecular biology facilitate targeting of chosen domains or scanning of the whole structure with spin labels. Comparison of dynamics, accessibility and distances at consecutive positions along the polypeptide chain is used in the determination of the secondary, tertiary and quaternary structure of proteins, which is of enormous importance in the post-genomic era. It is likely that the ease of determination of relative orientation of known domain motifs will make ESR a method of choice in high-throughput structural biology.

Technical advances in ESR, which include new probes, FTESR, higher magnetic fields, increase in absolute sensitivity, spectral dispersion and diversity of applications bode well for the continued development of ESR spectroscopy. Lastly, the development of powerful computational simulations makes ESR user-friendly and increases the number of ESR practitioners outside the die-hard community of spectroscopists.

LIST OF SYMBOLS

A	hyperfine interactions
A	peak-to-peak amplitude
$\boldsymbol{A}$	hyperfine interaction tensor
$A_{\max}, A'_{zz}$	maximum hyperfine splitting
a_0, A_0	isotropic hyperfine splitting
c	microwave field conversion factor
C'/C	central manifold line-height ratio of the V'_2 spectrum
D	diffusion tensor
$D_\perp, D_\parallel$	elements of diffusion tensor for motion parallel and perpendicular to the z-axis of a nitroxide
E	energy
f	resonant frequency of a spin
$f_\parallel, f_\perp$	frictional coefficients
$\boldsymbol{g}$	Zeeman interaction tensor
g_{eff}	effective g-value
H, H_0	magnetic field strength
$h, \hbar$	Planck's constant
H_1	microwave field
H_c	center field of a spectrum
H_m	modulation amplitude
H_{res}	resonant field
$I_0(H_{\text{res}})$	amplitude of the resonance line
J	coupling strength
L	directional cosine matrices
L, C, H	turning points of the spectra, $\theta = 0^\circ$

L''/L; H''/H	line-height ratios of STESR line shape
M_2	second moment of the central resonance
m_I	nuclear spin quantum number, nuclear manifold
P	microwave power
P'/P	line-height ratios of V_2' STESR spectra
$P_{1/2}$	half-saturation power
Q	resonator quality factor
r_{dd}	interspin distance
S	electron spin
S	order parameter
T_1	spin–lattice relaxation time
T_1^{eff}	effective spin–lattice relaxation time
T_2	spin–spin relaxation time
T_2^{eff}	effective spin–spin relaxation time
$V(m_I)$	peak-to-peak height of a given nuclear manifold resonance
V_0	absorption spectrum
V_1	first-derivative spectrum
V_2'	second-derivative, 90° out-of-phase display
W_x	rate of bimolecular collisions
$Y(H)$	electron spin resonance spectrum
β	Bohr magneton
ΔH_m	line width at half-height of a given nuclear manifold resonance line
ΔH_{pp}	peak-to-peak resonance line width
$\Delta\theta$	width of Gaussian angular distribution
Δw_{AB}^0	difference in resonant frequencies between spins A and B
η	resonator filling factor
η	viscosity
γ	magnetogyric ratio
Γ	width (at half-height) of the resonance
μ	magnetic moment of an electron
ν	Microwave frequency
w	Larmor frequency
Ω	orientational distribution
π	dimensionless accessibility parameter to relaxants
π	normalized solvent accessibility to various quenchers
Φ	differential accessibility to polar and nonpolar relaxants
$\rho(\theta)$	probability of the spins being orientated at angle θ with respect to the magnetic field
τ^{eff}	effective rotational correlation time
$\tau^{eff}(m_I)$	effective correlation time obtained from the STESR calibration curves of P'/P ratios
τ_{ex}	exchange time
$\tau_\perp$	correlation time for rotation about axis perpendicular to nitroxide z-axis
τ_r	rotational correlation time
τ_r^{iso}	isotropic rotational correlation time
$\tau_\parallel$	correlation time for rotation about the nitroxide z-axis
θ_c	cone angle
θ_0	center of Gaussian angular distribution
θ, ϕ	axial and azimuthal polar angles

ABBREVIATIONS AND ACRONYMS

ADP	Adenosine Diphosphate
AFC	Automatic Frequency Control
AMPPCP	Adenosine Methylenetriphosphate
AMPPNP	Adenosine Imidotriphosphate
ATP	Adenosine Triphosphate
ATPase	Adenosine Triphosphatase
ATPγS	Adenosine Thiotriphosphate
CROX	Potassium Tris(oxalatochromate)
DEER	Double Electron–Electron Resonance
DPPH	Diphenylpicrylhydrazyl
DR	Dielectric Resonator
ELDOR	Electron–Electron Double Resonance
ENDOR	Electron–Nuclear Double Resonance
ESR	Electron Spin Resonance
FID	Free Induction Decay
FTESR	Fourier Transform Electron Spin Resonance
GAPDH	Glyceraldehyde Dehydrogenase
HSE	Heisenberg Spin Exchange
LGR	Loop Gap Resonator
NAD	Nicotinamide Adenine Dinucleotide
NiAA	Nickel(II) Acetylacetonate
NiEDDA	Nickel(II) Ethylenediaminediacetate
NMR	Nuclear Magnetic Resonance
PADS	Peroxylamine Disulfonate
SDSL	Site-directed Spin Labeling
SECSY	Spin-echo Correlation Spectroscopy
SEESR	Spin-echo Electron Spin Resonance
SLE	Stochastic Liouville Equation
STESR	Saturation Transfer Electron Spin Resonance
TnC	Troponin C

TnI	Troponin I
TOAC	2,2,6,6-Tetramethylpiperidine-1-oxyl-4-amino-4-carboxylic Acid
UV	Ultraviolet
2-D	Two-dimensional

Fluorescence spectroscopy and its multiple applications to the life sciences have undergone rapid development. This is due to numerous technical advances in both instrumentation and methods of data analysis as well as to a vast proliferation of basic techniques. Applications of fluorescence spectroscopy to protein and peptide analysis are governed by three principal factors: the dynamic nature of the signal, its localized nature, and its redundancy. Although these features can complicate interpretation of the experimental result, they also can be exploited to obtain unique structural and dynamic information. The availability and simplicity of basic data acquisition and analysis are important practical features behind the popularity of fluorescence as compared to other spectroscopic techniques. Yet this simplicity does not appear to compromise its advantages. This article is intended first to provide an overview of the fluorescence phenomenon in proteins, and second to illustrate applications of fluorescence spectroscopy in advanced (but not necessarily high-tech) studies. Three areas of protein studies, namely protein–ligand interactions, protein folding and studies of membrane proteins, have been chosen to demonstrate key advantages of fluorescence spectroscopy: it is sensitive, versatile, and it lends itself readily to fast data acquisition.

1 INTRODUCTION

Fluorescence spectroscopy and its multiple applications to protein analysis, and to the life sciences in general, have undergone rapid development during the past decade. This progress appears to be driven on two levels. First, numerous technical advances in time resolution, methods of data analysis, and improved instrumentation have enabled researchers to probe the structural and dynamic features of proteins, membranes and nucleic acids, to acquire multidimensional (space–time) microscopic images of the distributions of various molecules in cell cultures, to follow conformational changes of single molecules, etc. These developments, pioneered by a handful of research groups, have spilled over into multiple areas as diverse as basic analytical chemistry and practical clinical applications.

The second, and sometimes under-appreciated, level of development of fluorescence spectroscopy in studies of biological macromolecules involves the proliferation of the basic technique. This progress is driven mainly by researchers whose primary scientific interests lie well outside the field of spectroscopy, and who, while admiring the elegance of the custom-designed multiphoton excitation experimental scheme, might not necessarily want to implement one in their own laboratory. Instead, they will use a commercially available fluorimeter, almost standard equipment these days in many laboratories involved in biochemical and biophysical studies. Nevertheless, their studies have produced not only numerous answers to a variety of important biological problems but have broadened the range of fluorescence techniques as well.

The availability and simplicity of basic data acquisition and analysis are important practical features behind the popularity of fluorescence as compared to other spectroscopic techniques. Yet this simplicity does not appear to compromise its main advantages, one of which, exceptional sensitivity, allows routine detection of fluorescent substances on a subnanomolar scale on the one hand, and provides the ability to collect data in a kinetic regime during fast submillisecond reactions on the other. Applications of fluorescence spectroscopy to protein and peptide analysis are governed by three principal factors: (1) the dynamic nature of the signal, (2) its localized nature, and (3) its redundancy. Fluorescence is a dynamic phenomenon and the

lifetime of the excited state is sufficient for a variety of chemical and physical reactions to take place prior to emission. The usual nanosecond time-window of fluorescence is normally shorter than that of other dynamic techniques (e.g. nuclear magnetic resonance (NMR), electron paramagnetic resonance (EPR)). Fluorescence spectroscopy is essentially a probe technique sensing changes in the local environment of the fluorophore, which distinguishes it from generalized techniques, such as calorimetry, far-ultraviolet circular dichroism (CD), and infrared (IR) spectroscopy. Also, various possibilities of structural rearrangements in the environment of the fluorophore may lead to a similar fluorescence signal. None of these features taken alone is either beneficial or detrimental. Although they can complicate interpretation of the experimental result, they also can be exploited to obtain unique structural and dynamic information.

Fluorescence spectroscopy and its various applications have been reviewed over the years in several excellent publications, e.g. basic[1] and advanced textbooks,[2,3] monographs[4,5] and specialized editions.[6,7] This article is not intended as a condensed version of the material in those contributions. Instead it focuses on two tasks: first to provide an overview of the fluorescence phenomenon in proteins, and second to illustrate applications of fluorescence spectroscopy in state-of-the-art (but not necessarily high-tech) studies. The goal is to concentrate on fundamental principles and advanced applications.

1.1 What is Measured in a Protein Fluorescence Experiment?

The four principal aspects of the fluorescence phenomenon are: energetics, probability, kinetics and vectoriality. Each can be studied experimentally by measuring the intensity of the emitted light as a function of wavelength, orientation of polarizers, time elapsed since excitation, etc. Therefore the question posed in the title of this section has a simple answer – fluorescence intensity, I. Let us now consider how this basic measurement can be converted into multiple measures characterizing various aspects of fluorescence.

Intensity measured as a function of wavelength (or wavenumber) comprises the fluorescence spectrum. The position of the emission spectrum reflects changes in energetics of the excited and ground state between excitation and emission of a photon. In practice the position of the emission band is expressed as a wavelength of the maximum λ_{max}.

Total intensity of the emission at all wavelengths is related to fluorescence quantum yield, q. Quantum yield is defined as a ratio of the number of emitted quanta to the number of absorbed quanta. It reflects the probabilities of various photochemical and photophysical processes leading to radiational or radiationless deactivation of the excited state.

The time-dependence of fluorescence intensity following excitation in the ensemble of fluorophores is related to the excited state lifetime, τ. This kinetic parameter characterizes the average time a molecule spends in the excited state before emitting the photon:

$$I(t) \sim e^{-t/\tau}$$

More often than not, fluorescence intensity follows a more complex law of decay than simple exponential (see section 2.3). Two experimental schemes allowing determination of the fluorescence lifetime are known as pulse domain and frequency-modulation domain spectroscopy (for more on lifetime measurements see Lakowicz[1,3]).

Anisotropy, r (along with the interchangeably related polarization, P), is a vectorial characteristic reflecting changes in the direction of the emission transition moment with regard to the excitation transition moment. Anisotropy is affected by the relative orientation of the dipoles in the ground and excited states and by changes in the orientation of the excited state with respect to external (laboratory) coordinates due to the molecule's rotation or radiationless energy transfer to another molecule prior to emission. Anisotropy and polarization are defined in Equations (1) and (2) by intensities of vertically ($I_{\parallel}$) and horizontally ($I_{\perp}$) polarized light measured when excitation light is vertically polarized:

$$r = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + 2I_{\perp}} \tag{1}$$

$$P = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + I_{\perp}} \tag{2}$$

Anisotropy and polarization can be measured in a steady-state and kinetic regime (for more on anisotropy measurements and their applications see Steiner[8]).

The ratio of intensities in the absence, I_0, and in the presence, I, of an external quencher at concentration $[Q]$ is used to determine a Stern–Volmer constant, K_{SV}, as shown in Equation (3):

$$\frac{I_0}{I} = 1 + K_{SV}[Q] \tag{3}$$

If the changes in lifetime follow the changes in intensity, the quenching is called dynamic and the biomolecular quenching rate, k_q, can be determined using Equation (4):

$$\frac{\tau_0}{\tau} = 1 + K_{SV}[Q] = 1 + k_q\tau_0[Q] \tag{4}$$

The biomolecular rate gives information on chromophore accessibility to the aqueous phase and on the distribution

of charges surrounding the fluorophore if a charged quencher is used. In the case of static quenching, only the intensity decreases with addition of quencher while the lifetime remains the same (for more on quenching measurements and their applications see Eftink[9]).

Another useful parameter is the efficiency of the long-range energy transfer, E, between an initially excited molecule (donor) and another chromophore (acceptor). Efficiency of this dynamic process can be calculated from either intensity or lifetime of donor alone (I_D, τ_D) and in the presence of acceptor (I_{DA}, τ_{DA}) as shown in Equation (5):

$$E = 1 - \frac{I_{DA}}{I_D} = 1 - \frac{\tau_{DA}}{\tau_D} \tag{5}$$

Efficiency of transfer is used to estimate the distance between donor and acceptor, R, according to Förster theory, as shown in Equation (6):

$$E = \frac{R_0^6}{R_0^6 + R^6} \tag{6}$$

where R_0 is a Förster distance for half-transfer and is a characteristic of a donor–acceptor pair and its environment (for more on energy transfer measurements and their applications see Cheung,[10] Wolber and Hudson,[11] and Wu and Brand[12]).

It is important to keep in mind that neither distance, nor quenching rate, nor strictly speaking lifetime are *measured* in a fluorescence experiment. All these important parameters are derived from the basic measurements of intensity, using more or less restrictive assumptions (e.g. absence of nonspecific perturbations after introduction of the acceptor fluorophore, or fluorescence decay being adequately described by a sum of exponential components) and therefore are to some extent model-dependent.

2 PROTEIN FLUORESCENCE

2.1 Spectral Properties of Protein Fluorophores

2.1.1 Tryptophan and its Derivatives

Absorption of tryptophan is due to $\pi \rightarrow \pi^*$ transitions in the indole ring **(1)**. The short wavelength band (220 nm) is due to the ^1B_b transition while the long wavelength band (260–290 nm) consists of the two overlapping transitions ^1L_a and ^1L_b with vectors almost perpendicular to each other. The ^1L_a transition is sensitive to the polarity giving rise to a slight shift in absorbance spectrum. The ^1L_a transition is believed to be the main contributor to the emission.

(1)

In aqueous solution tryptophan displays a wide, structureless fluorescence band with a maximum of about 350 nm and width of about 60 nm. It is worth noting that tryptophan fluorescence spectra measured under the same conditions but using different instruments may differ slightly in position of the maximum (348–353 nm), width and shape because of the differences in spectral calibration. Unfortunately, at present there are no generally accepted standards for the spectral calibration of instruments in the near-ultraviolet region. Because excitation leads to a substantial increase in the dipolar moment (about 4 D), shifts in the emission are much stronger. This shift is caused by the orientational relaxation processes involving the dipole of the chromophore and solvent dipoles. This sensitivity of tryptophan emission to polarity and mobility of environment makes tryptophan fluorescence an important tool in studies of protein structure and dynamics.

The absolute quantum yield of tryptophan in an aqueous environment was reported to be 0.13.[13] In most cases, however, a knowledge of the absolute value is not necessary and relative quantum yield is used instead. Tryptophan fluorescence is susceptible to the quenching by water which occurs with high activation energy (11–12 kcal mol^{-1}).[14,15] This leads to the frequently observed decreases in quantum yield upon denaturation when tryptophan becomes exposed to an aqueous environment. However, there are numerous exceptions to this rule because tryptophan fluorescence can also be quenched in a protein's native state.

Almost all polar protein groups can quench tryptophan fluorescence, to some extent.[14,16–21] Possible nonradiative processes include photoionization, intersystem crossing, exciplex formation, and excited state proton and excited state electron transfer. Aspartic and glutamic acid residues are effective dynamic quenchers in their neutral, but not charged, forms. Lysine and arginine are also dynamic quenchers, but are more effective when charged. Histidine at low pH appears to quench by formation of a stacking complex with the indole ring. The nonprotonated histidine is also able to quench tryptophan fluorescence, although with much-reduced efficiency. Disulfide is one of the strongest quenchers of tryptophan fluorescence, although single cysteine can be an effective quencher too. In addition, amide and peptide groups were shown to act as dynamic quenchers. In heme-containing proteins, long-range energy transfer quenching is important due to the spectral overlap

of tryptophan emission and heme absorbance. While such effects complicate the analysis of protein fluorescence, they can also be used to extract valuable structural information. For example, in membrane-bound cytochrome b_5, heme quenching of Trp-109 was used to estimate the distribution of distances between two protein domains.[22]

Tryptophan appears to be uniquely sensitive to quenching by a variety of substances, such as oxygen, iodide, bromide, acrylamide, succinimide, hydrogen peroxide, dichloroacetamide, pyridinium hydrochloride, NO_3^-, Cs^{2+}, Cu^{2+}, Pb^{2+}, Cd^{2+} and Mn^{2+}.[14,16,23] This sensitivity to quenchers allows determination of the accessibility of the tryptophan residues in proteins by quenching measurements.

The fluorescence decay of tryptophan does not follow a single exponential. Szabo and Rayner[24] had reported two decay times of 0.5 and 3.1 ns for tryptophan zwitterion in an aqueous environment at room temperature. The short-lived component has a blue-shifted spectrum. The heterogeneity of decay of tryptophan derivatives in fast-relaxing environments is attributed to the side chain rotamers. Decay becomes even more complex when solvent relaxation occurs on a nanosecond timescale (see section 2.3).

The existence of two overlapping transitions and energy transfer occurring predominantly from ^1L_b to ^1L_a complicates the appearance of the excitation polarization spectrum of tryptophan. In their classic work, Valeur and Weber[25] have resolved two transitions in the excitation spectrum of indole and tryptophan in frozen propylene glycol using polarization data. The limiting anisotropy of tryptophan depends on the excitation wavelength and is about 0.3 at 300 nm, and 0.2 at 270 nm. The spectral region in-between has several sharp bands, which are expected to shift depending on the solvent conditions, making the region from 280 to 300 nm difficult to use for polarization measurements.

An important emerging field in protein fluorescence is related to the use of spectrally enhanced protein mutants.[26] This approach takes advantage of tryptophan analogs with different photophysical properties incorporated as intrinsic fluorophores either by chemical synthesis or, biosynthetically, using tryptophan auxotroph *Escherichia coli* strains.[27,28] Three analogs are suggested to be most useful for studies of protein–protein and protein–nucleic acid interactions: 5-hydroxytryptophan **(2)**, 4-fluorotryptophan **(3)** and 7-azatryptophan **(4)**. 5-Hydroxytryptophan absorbance has a long wavelength shoulder going as far as 320 nm, allowing this fluorophore to be selectively excited in the presence of multiple normal tryptophan residues. In addition, when excited in this region 5-hydroxytryptophan has a high limiting

(2) **(3)** **(4)**

anisotropy, making it useful for polarization studies. 4-Fluorotryptophan is nonfluorescent, making a ''silent'' analog. It also has been used in nonfluorescence experiments because of its altered ground state dipole. 7-Azatryptophan has a dramatic change in quantum yield upon exposure to water, making it potentially useful in protein folding experiments.

2.1.2 Other Natural Fluorophores and Fluorescence Labels

A variety of biological molecules contain naturally occurring or intrinsic fluorophores. Tryptophan is the most highly fluorescent amino acid in proteins (see sections 2.1.1 and 2.2). It is so widely used that the term ''natural protein fluorescence'' is almost always associated with tryptophan fluorescence. The second most fluorescent amino acid is tyrosine, but its application is mostly limited to tryptophan-free proteins. Fluorescence of phenylalanine is weak and almost never used in protein studies. Another class of natural fluorophores consists of cofactors, NADH (reduced β-nicotinamide adenine dinucleotide) being the most prominent.

The fluorescence properties of NADH have been the subject of multiple studies.[29–31] In aqueous solution the quantum yield of fluorescence is low and the average lifetime is in the subnanosecond range due to stacked conformation of the molecule. Binding to liver alcohol dehydrogenase leads to a blue-shift in absorbance and fluorescence and an increase in quantum yield (see section 3.2). This effect is enhanced by formation of a ternary complex with the substrate analog isobutyramide. The lifetime distribution for NADH shifts into a nanosecond range and undergoes a complex change in binary and ternary complex, indicating the existence of an excited state reaction.[31]

The fluorescence properties of natural chromophores are frequently inadequate for certain studies. In these cases fluorophores foreign to the system under study but displaying improved spectral properties are chosen. These extrinsic fluorophores when covalently linked to a protein (usually at a cysteine or lysine side chain) are called fluorescence labels. Modern labeling procedures in combination with mutagenesis allow labels to be introduced selectively at a specific location in a protein. The *Handbook of Fluorescent Probes and Research Chemicals*[32] provides an excellent source of information on various dyes and labeling procedures.

Figure 1 Example of the experimental system requiring the use of fluorescence labels in protein studies. Neither intrinsic fluorescence nor conventional labeling can specifically probe the environment of the nascent chain (solid line) in the presence of ribosome–translocon complex (large ovals). To overcome this limitation Crowley et al.[34] have developed a way to biosynthetically incorporate NBD-labeled (small ovals) lysine residues in the nascent chain. Fluorescence of NBD dye is sensitive to the polarity of its environment and to addition of water-soluble quenchers, such as iodide. Combination of steady-state and phase-modulation measurements allowed differentiation between various possibilities of organization of the translocon complex. (Reproduced by permission of Cell Press.)

In an ingenious example of the use of a fluorescence label, the fluorescence properties of 6-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)aminohexonic acid (NBD) were utilized to determine the environment of the nascent chain in the translocon complex[33–35] (Figure 1). Emission of NBD is very sensitive to the properties of its environment: moving from an aqueous to apolar environment increases the lifetime and the quantum yield and causes blue-shift of emission. Nascent chains, however, cannot be labeled selectively in the presence of ribosomes and endoplasmic reticulum-membrane proteins. Site-specific positioning of the probes in the nascent polypeptides can only be achieved by using aminoacyl-tRNA analogs that incorporate amino acids labeled with suitable probes into the chain as it is being synthesized. Johnson et al.[36] devised a method for preparing analogs in which probes are covalently attached to the side chain of lysine in Lys-tRNA. The validity of the approach was demonstrated by showing that the modified lysines were incorporated successfully into proteins in vitro. Since different models of translocon organization differ primarily in the exposure of the nascent chain to the cytoplasm, they could be tested directly by determining whether fluorescent dyes in the nascent chains of membrane-bound ribosomes were accessible to water-soluble quenchers in the cytoplasm. NBD dyes located at different positions along the nascent chain pathway in free ribosomes were each found to have very short fluorescence lifetimes (less than a nanosecond) and to be quenched when iodide ions were added to the solvent.[34] Thus, the nascent chain is in an aqueous environment and exposed to the cytoplasm when bound to a free ribosome. But when iodide ions were added to membrane-bound samples of the same ribosome–nascent-chain complexes, the Stern–Volmer constant for fluorescence quenching was reduced by an order of magnitude. This observation led to the conclusion that, in early stages of translocation, the nascent chain is tightly surrounded by the ribosome and membrane components of the endoplasmic reticulum.

2.2 Spectral Classes of Tryptophan Residues

The position of the maximum of the fluorescence spectrum of tryptophan residues in proteins varies from 307 to 353 nm. According to the model of discrete states of Burstein et al.[37,38] there are five most probable spectral forms of tryptophan residues (Figure 2). Formation of various exciplexes (complexes in the excited state) and subsequent dipole relaxation is believed to cause the red-shift of emission.

Spectral form A corresponds to the emission of the unperturbed indole chromophore in the extremely nonpolar environment inside the protein globule. Such emission in its pure form was found only in azurin, however the class A spectrum contributes to the total spectra of a few other proteins. Azurin, a small globular metal-binding protein, contains a single tryptophan residue that displays a rather unusual fluorescence spectrum. It is extremely blue-shifted, with a main maximum of about 307 nm, and it possesses a distinct vibrational structure. The emission from the ^1L_b state is assumed to contribute significantly in the spectrum, giving rise to mirror symmetry of emission and absorbance.

Figure 2 Normalized fluorescence spectra of tryptophan residues belonging to five spectral classes A, S, I, II and III according to Burstein.[38] Extreme variability of the emission of the indole fluorophore, depending on polarity and mobility of its environment, makes tryptophan fluorescence a sensitive tool in protein analysis. (Reproduced by permission of ONTI NCBI.)

Freezing an azurin solution does not change the position of its fluorescence spectrum.

Spectral form S corresponds to the emission of the indole chromophore located in the relatively nonpolar environment inside the protein globule and forming a 1:1 exciplex with some polar protein group. The S spectrum has a maximum at 316–317 nm and shoulders at 305–307 nm and 320–330 nm. It is of interest that a pure S spectrum has never been reported, but is always accompanied in proteins by a contribution from the class I spectrum (see below), which corresponds to a 2:1 exciplex. For example, types S and I contribute almost equally to emission of L-asparaginase.[39] It is assumed that during the excitation lifetime the 2:1 complex is formed to a different extent in different proteins depending on the mobility and abundance of polar groups in the tryptophan environment. Freezing of the solution does not shift class S spectra, indicating that a 1:1 complex can be formed at temperatures as low as −196 °C.

Spectral form I corresponds to the emission of the indole chromophore in the somewhat polar but perhaps rigid environment inside the protein globule, forming a 2:1 exciplex with two neighboring polar protein groups. The fluorescence spectrum of class I has a maximum at about 330 nm, width of about 50 nm and no vibrational structure. A class I spectrum is observed for actin, chymotrypsin and tetrameric melittin under high-salt conditions.

Spectral form II corresponds to the emission of the indole chromophore at the protein surface. It is assumed to be in contact with bound water and other polar groups. The fluorescence spectrum of class II is also structureless, but red-shifted as compared to class I. The position of the maximum is at about 340 nm and the width is about 55 nm. Many proteins contain tryptophan residues of this class, e.g. human serum albumin and myosin.

Spectral form III corresponds to the emission of the indole chromophore at the protein surface in contact with free water molecules. The spectrum of class III, with its maximum at about 350 nm and width of about 60 nm, nearly coincides with the spectrum of free tryptophan. Tryptophan residues of spectral class III very seldom occur in the native proteins, but are typical for unfolded states.

Due to their location on the protein interface, tryptophans of spectral classes II and III are easily accessible to external quenchers in aqueous phase. At the same time, tryptophans of classes A, S and I are located inside the protein structure and are poorly accessible to water-soluble quenchers. Freezing of the water solution of a protein shifts the fluorescence spectra of classes I, II and III towards shorter wavelengths due to the immobilization of their polar environment. It should be noted that the model of discrete states of tryptophan residues in proteins is a statistical one, i.e. tryptophan residues located in environments that result in one of the five likeliest spectral forms is more probable than finding them in intermediate environments.

Most proteins, however, exhibit spectra that contain contributions from different classes. To resolve those contributions a fitting procedure was designed based on a parameterized description of fluorescence spectra. At the heart of this analysis lies approximation of emission spectra with the log-normal distribution[40] usually expressed on the scale of wavenumbers, ν, as shown in Equations (7) and (8):

$$I(\nu) = I_{\max} \exp\left(-\frac{\ln 2}{\ln^2 \rho} \ln^2 \frac{a-\nu}{a-\nu_{\max}}\right) \qquad \text{for } \nu < a \qquad (7)$$

$$I(\nu) = 0 \qquad \text{for } \nu \geq a \qquad (8)$$

where $I_{\max}$ is intensity at position of maximum, $\nu_{\max}$, and $\rho = (\nu_{\max} - \nu^-)/(\nu^+ - \nu_{\max})$ is spectral asymmetry. Parameter $a = \nu_{\max} + (\nu^+ - \nu^-)\rho/(\rho^2 - 1)$, where ν^- and ν^+ are the positions on the wings of the spectrum where intensity equals half of $I_{\max}$. The total of four fitting parameters ($I_{\max}$, $\nu_{\max}$, ν^-, ν^+) per spectrum is adequate to get a unique solution, but to resolve two or more spectral components additional constraining factors are required. They are obtained from the empirical observation that width and position of the maximum of tryptophan derivatives in isotropic media are related as shown in Equations (9) and (10):

$$\nu^+ = 0.8308\nu_{\max} + 7071\ \text{cm}^{-1} \qquad (9)$$

$$\nu^- = 1.1768\nu_{\max} + 7681\ \text{cm}^{-1} \qquad (10)$$

An advanced version also utilizes spectra collected at different concentrations of quenchers to increase reliability and robustness of fit.[41]

In a simplified version of the analysis, the spectrum is fitted to a single log-normal distribution (often on a wavelength scale) to recover full width at half-height, γ, and position of maximum, $\lambda_{\max}$.[37,42] If the point on a spectral width vs position plot appears above the standard line for tryptophan in model isotropic media, several spectral classes are present. For example, a conformational change in bee venom peptide melittin can be followed by position-width analysis of steady-state spectra of Trp-19 (Figure 3). At low ionic strength melittin exists as a mainly unstructured monomer with highly exposed tryptophan (spectral class III). Additions of salt induce a monomer–tetramer transition, resulting in the removal of the tryptophan side chain from the aqueous phase (spectral class I). Intermediate states have significantly broadened spectra and follow theoretically

Figure 3 Example of protein conformational transition followed by spectral changes in tryptophan emission spectrum. Steady-state fluorescence spectra were fitted to a log-normal distribution to recover position of maximum and width. Open squares represent discrete states of tryptophan residues in proteins belonging to spectral classes I, II and III. Fluorescence is heterogeneous when the position–width point is above the straight line. Closed circles represent titration of melittin solution with KCl, which in this peptide causes conformational change from monomer to tetramer. This transition results in changes of exposure of the tryptophan residue from completely exposed (class III) directly to buried (class I), without going through the intermediate state (class II).

predicted semi-arc patterns.[37] Several advantages of position–width analysis over simple analysis of λ_{max} are immediately obvious. First, it is clear that spectral class II is not involved in the transition, because the spectra in the mid-transition are too broad, although they have the same maximum as II. Second, λ_{max} is not changed appreciably in the last stages of transition, and completion of conformational change is best judged by the narrowing of the spectral width. It should be emphasized, however, that despite its sensitivity the analysis of spectral position cannot be used to quantitate the conformational change or ligand binding, because λ_{max} is not a linear response function (see section 3.2). To calculate the thermodynamic parameters one should use one of the linear response spectroscopic functions as the observable, e.g. the intensity at any constant wavelength.

2.3 Protein Dynamics and Heterogeneity of Fluorescence Decay

It has long been noted that even for single tryptophan-containing proteins, fluorescence decay does not follow simple exponential kinetics.[43] Due to the nature of the lifetime analysis certain assumptions have to be made, which usually means that complex decay is assumed to be described by a number of exponential components. As instruments become more sophisticated, more components have been reported and even the distributions of lifetimes have been utilized to fit the data.[44–47] Regardless of the mode of analysis (discrete exponentials or distributions), the main empirical result is that it takes several parameters to describe fluorescence decay. Exponentials, however, do not form an orthogonal system of functions and multiple solutions can exist which fit the same data equally well. Therefore, one should use the term multi-exponential decay with caution, keeping in mind that the exact nature of nonexponentiality might not be known, and that recovered components may or may not have a physical meaning.

Interpretations of complex decay of tryptophan fluorescence fall into two main categories: ground state heterogeneity (e.g. rotamer model) and excited state reaction (e.g. relaxation model). Based mainly on model studies done with tryptophan and tyrosine derivatives, several groups have suggested that different rotameric forms are responsible for nonexponential decay.[24,48,49] In recent years there has been a breakthrough in understanding the mechanisms governing the decay of rotamers of restricted indole derivatives.[20,50,51] However, those model studies were carried out in isotropic fast-relaxing media. Proteins, in contrast, are heterogeneous systems with a hierarchy of internal motions that cover a wide range of correlation times, including the nanosecond time window of fluorescence. On the other hand, the excited state reaction approach relies on protein dynamics to convert electronically excited indole into other spectroscopic species. More specifically, the relaxation model assumes that such reaction involves reorientation of polar groups surrounding tryptophan in a protein.[52–54] Neither of the models has been unequivocally proven for any specific protein.

Recently it has been suggested that excitational dependence can be used as a criterion to distinguish between alternative mechanisms causing deviations from exponential decay in proteins.[55] This approach takes advantage of considerations developed to explain inhomogeneous broadening of the electronic spectra of dye molecules caused by the distribution in configurational energy in solvate.[56–58] Such systems are characterized by the following features: (1) decay is nonexponential, (2) decay depends on the excitation wavelength, λ_{exc}, and becomes faster at longer λ_{exc} (red-edge effect), and (3) in extreme cases a rising component in intensity (negative pre-exponential) is observed at the longer emission wavelength.

An abbreviated summary of these features for fluorescence decay in simple model systems and in proteins

Table 1 Summary of heterogeneity of fluorescence decay of indole fluorophore in model media and in proteins

System	Is fluorescence decay monoexponential?	Does decay depend on excitation wavelength?	Is the rising intensity component observed?	Nature of heterogeneity of decay
Indole in water or methanol	Yes	No	No	None (no rotamers, fast relaxation)
Indole in 40% glycerol	No (2 components)	Yes	No	Mild relaxation effects
Indole in 90% glycerol	No (3 components)	Yes	Yes	Relaxation effects
Trp in water	No (2 components)	No	No	Rotamers
Trp in 40% glycerol	No (3 components)	Yes	No	Rotamers + mild relaxation effects
Proteins (single tryptophan residue)	No (2–4 components, usually 3)	Both possibilities can be observed	No (with rare exceptions)	? (possible combination of several mechanisms)

is presented in Table 1 (Ladokhin, unpublished).[55] Slowing of dipolar relaxation by additions of glycerol leads to progressive heterogeneity and excitational dependence in fluorescence decay of the indole molecule, which obviously lacks rotameric forms. Note that deviation from exponentiality starts at low glycerol concentrations, before the negative pre-exponential could be observed under commonly used instrumental conditions (the width of the excitation pulse was 60 ps). As described above (see section 2.1.1), tryptophan zwitterion in aqueous solution shows a double exponential decay due to rotameric forms.[24] In this case, however, the decay is independent of the excitation wavelength. When a tryptophan molecule is placed under conditions of mild viscosity, decay becomes more complex, and in this case excitational dependence can be detected. In proteins the excitation dependence can be small or significant and the negative exponential normally is not observed unless four exponential components are used in the analysis, and then only for a few proteins. Melittin in methanol, when it is helical and monomeric, constitutes an exception when a negative pre-exponential is observed with one of the three components.[55] This overall behavior of proteins is consistent with contributions from both ground state heterogeneity and excited state reactions.

The model studies presented above indicate the importance of protein dynamics for interpretation of fluorescence decay in proteins. This is also true for other fluorescence parameters, such as dynamic depolarization, biomolecular quenching rate, temperature-induced quenching in the native state, red-edge excitation shift, distribution of distances calculated in energy transfer experiments, etc. In a sense all protein fluorescence spectroscopy is influenced by the dynamic nature of protein. Further understanding of this link will allow one to solve the reverse task and to determine dynamic parameters of protein structure from its fluorescence.

3 FLUORESCENCE STUDIES OF PROTEIN CONFORMATION AND INTERACTIONS

3.1 Protein Folding

Fluorescence spectroscopy plays a major role in protein folding studies.[59,60] For example, the fluorescence increase of 8-anilino-1-naphthalensulfonic acid was used to identify the molten globule state during refolding of various proteins,[61] and intrinsic fluorescence, along with other methods, was utilized to provide evidence for a two-state transition in chymotrypsin inhibitor.[62] A variety of fluorescence observables can be used to follow denaturation or renaturation of the protein native structure induced by changes in temperature, pH or additions of solutes. One such example has already been discussed in previous sections – changes in the emission bandshape following tetramerization of melittin was presented in Figure 3 (see section 2.2). Another example is the change in emission maximum and polarization of tryptophan fluorescence of apohorseradish peroxidase upon addition of a denaturing agent, guanidinium chloride.[63] Unfolding of this protein results in increased exposure of a single tryptophan residue to aqueous environment revealed by the fluorescence red-shift (Figure 4). Increased mobility of the tryptophan due to the loss of native packing contacts upon denaturation results in the parallel loss of emission polarization. Note that an excitation wavelength of 300 nm was used for polarization measurements to avoid strong depolarization (insert, Figure 4), due to overlapping ^1L_a and ^1L_b transitions at the shorter wavelengths (see section 2.1.1). In addition to emission maximum and polarization, a number of other parameters (e.g. intensity, lifetime distribution, Stern–Volmer constant, efficiency of the radiationless energy transfer) can be utilized in steady-state protein folding studies. But the advantages of fluorescence studies of folding are demonstrated most vividly, perhaps, with kinetic measurements.

Figure 4 Example of chemical-induced protein unfolding studied by fluorescence spectroscopy.[63] Additions of guanidinium result in red-shift of fluorescence and in decrease of emission polarization of a single tryptophan in the apohorseradish peroxidase. Insert shows the excitation polarization spectrum. (Reproduced by permission of the Biophysical Society.)

Among the spectroscopic methods used in combination with stopped-flow mixing, fluorescence is probably the simplest, yet most sensitive and widely employed. Recent years have been marked by considerable advances in both mixing techniques and kinetic acquisition of spectroscopic data. Application of advanced continuous-flow mixing to follow the energy transfer from tryptophan and tyrosines to heme in cytochrome *c* has allowed probing of the barrier-free submillisecond transition between the initially collapsed state and the native state. Using a combination of both continuous-flow microsecond mixing and conventional stopped-flow mixing, Shastry et al.[64] demonstrated how continuous kinetic data from 50 μs to >10 s after initiation of the folding event can be obtained (Figure 5). Ramsay et al.[65,66] have developed a fluorimeter/CD photometer hybrid allowing global changes in secondary structure and local changes in the tryptophan environment to be determined simultaneously for the same sample.

Beechem et al.[67–69] have pioneered the development of another important technical advance in spectroscopic analysis of fast kinetic effects by combining the advantages of time-resolved spectroscopy with kinetic stopped-flow measurements. This double-kinetics technique achieves simultaneous measurement of changes in fluorescence on both the picosecond/nanosecond and millisecond timescale. After initiation of folding the decay of tryptophan anisotropy is measured in millisecond intervals of time, thus allowing the determination

Figure 5 Example of protein folding kinetic measurement utilizing tryptophan fluorescence.[64] (a) Refolding of acid-unfolded horse cytochrome *c* was followed on the submillisecond timescale in a continuous flow capillary mixing apparatus. (b) Combination of continuous flow (CF) and conventional stopped-flow (SF) experiments allows collection of data over a wide range of time (symbols) and determination of the five kinetic phases with correlation times ranging from tens of microseconds to tens of milliseconds (solid line). (Reproduced by permission of the Biophysical Society.)

of tryptophan rotation mobility "in real time" during protein refolding. This allows ascertaining the timescale associated with tryptophan "packing" into intermediate structures and eventually into the final native state. Such experiments can also follow the changes in lifetime due to different fluorescence quenching in the folded and unfolded state. If two fluorophores capable of making a donor–acceptor pair are introduced, such studies can be used to determine the changes in distance between labeled sites on the millisecond timescale.

In addition to the water-soluble systems discussed above, fluorescence spectroscopy is now being employed to study folding of membrane proteins[70–74] (see section 3.3).

3.2 Protein–Ligand Interactions

There are two principal possibilities that can be exploited to study protein–ligand interactions. The fluorescence of either the protein or the ligand can change upon binding. These two situations require somewhat different data analysis procedures.[75] When changes in the fluorescence of a protein are observed, the fluorophore may be one or more of the intrinsic tryptophan residues, or it may be the covalently attached or tightly bound fluorophore.

Tryptophan is a relatively sensitive fluorophore. Its spectrum can vary more than 40 nm (see section 2.2) and its quantum yield in proteins and peptides ranges from virtually zero to almost 0.5. The latter change is usually accompanied by a corresponding variation in the excited state lifetime. The binding of a ligand to a protein may directly affect the fluorescence of a tryptophan residue by acting as a quencher (i.e. by a collisional or energy transfer mechanism) or by physically interacting with the fluorophore and thereby changing the polarity of its environment and/or its accessibility to solvent. Alternatively, a ligand may bind at a site remote from the tryptophan residue and act via a generalized mechanism by inducing protein conformational change, which alters the microenvironment of the tryptophan. Both direct and generalized effects may result either in enhancement or quenching of fluorescence and/or in shifts in the spectrum to the red or blue. If there are multiple tryptophan residues in a protein, this will make it difficult to assign any fluorescence changes to a specific residue. To overcome this limitation, structural studies are now being conducted on single tryptophan-containing mutants. However, for many other purposes, e.g. the thermodynamics of ligand binding, the presence of multiple fluorophores is a minor consideration. More important is the fact that the observable be a linear-response function.

3.2.1 Linear-response Spectroscopic Techniques

Consider the simple case of a two-state equilibrium (the general case is described by Toptygin and Brand[76]) that can be followed by a change in a certain spectroscopic parameter S that changes from a value $S_{\min}$ in the absence of binding to $S_{\max}$ when all of the molecules are bound. The fractional change in the spectroscopic parameter f_{signal}, defined as $f_{\text{signal}} = (S - S_{\min})/(S_{\max} - S_{\min})$, is often used to characterize the extent of completion of the binding reaction. The fraction of bound molecules $f_{\text{bound}} = P_{\text{bound}}/P_{\text{total}}$ will coincide with f_{signal} only if S is a linear-response function. For that case, the signal observed can be represented as a linear combination of molar fractions of bound and free molecules weighted by their corresponding molar spectroscopic characteristics, s_{bound} and s_{free}, as shown in Equation (11):

$$\begin{aligned}\frac{S}{P_{\text{total}}} &= f_{\text{bound}}s_{\text{bound}} + f_{\text{free}}s_{\text{free}} \\ &= f_{\text{bound}}s_{\text{bound}} + (1 - f_{\text{bound}})s_{\text{free}}\end{aligned} \tag{11}$$

Not all spectroscopic data satisfy this equation. For example, the following spectroscopic parameters are not linear-response functions and therefore cannot be utilized for measurements of binding: position of maximum of the fluorescence spectrum and related parameters such as center of weight, center of the chord at any intensity level, or ratio of intensities on the wings; fluorescence polarization (or anisotropy); intensity at the maximum of the spectrum; the phase ϕ and modulation m from frequency domain fluorimetry; fluorescence decay curve collected to a constant peak; and transmittance from spectrophotometric measurements. Parameters that are linear-response functions and that can be utilized for measurements of binding include the following: fluorescence quantum yield; steady-state intensity at a constant wavelength I_{ss}; $I_{ss}m\cos\phi$ and $I_{ss}m\sin\phi$;[76] fluorescence decay curve collected to a constant time; vertical and horizontal components of fluorescence intensity (and of any other angle too); and absorbance from spectrophotometric measurements.

In addition to general rules that apply to all binding experiments, there are some peculiarities relevant to specific aspects of experimental schemes. For example, in membrane partitioning experiments there is an explicit assumption that s_{bound} does not depend on the completion of binding or on the number of bound molecules per lipid vesicle. However, in the case of fluorescence, the intensity can be a nonlinear function of bound molecules due to nonradiative energy homotransfer or other self-quenching mechanisms. This possibility is often overlooked during the analysis of complex membrane partitioning. Various spectroscopic and nonspectroscopic methods to quantitate binding to membranes are discussed elsewhere.[77]

Toptygin and Brand[76] have developed special software to fit multiple families of titration data obtained with any of the linear-response spectroscopic techniques. The SPECTRABIND program uses model equilibrium equations as constraints to determine the basic components associated with the actual chemical species and their concentrations. A statistical test is used to discriminate between adequate and inadequate models, the decision being independent of any knowledge and/or assumptions about the spectroscopic characteristics of chemical species. This approach is aimed at systems involving multiple interactions, where the changes in spectroscopic signal cannot be attributed to a single interaction. An example

of the application of SPECTRABIND to the interaction of horse liver alcohol dehydrogenase with NADH and isobutyramide is given in Figure 6.[76] Fluorescence spectra of NADH in various binary and ternary complexes recovered from the same titration data sets using two different binding models are presented. Both models assume that the two binding sites (one on each of the identical subunits of the protein dimer) are identical and independent in terms of association constants. Figure 6(a) contains results obtained under the additional generic assumption that binding to the two sites is also spectroscopically independent. The three essential spectroscopic species correspond to a free NADH (N), its binary complex with the protein subunit (SN), and its ternary complex with additional isobutyramide (SNI). Protein (S) and isobutyramide (I) by themselves produce negligible signal, while the background signal (B) contains a sharp peak of Raman scattering band of water. The model from Figure 6(b) does not assume spectroscopic independence of binding sites and contains multiple species of various combinations of the entire dimeric protein (P) with one or two NADH and isobutyramide molecules. The association constants for each binding step are also determined.[76] This example illustrates the ability of the SPECTRABIND program to analyze complex binding equilibria.

The basic limitation of spectroscopic techniques for studying protein–ligand interactions is the necessity for a sufficiently strong change in some spectroscopic signal. The lack of an adequate signal can hinder rigorous quantitative determination of binding. To overcome this limitation in studies of nucleic acid-binding proteins, Jezewska et al.[78,79] applied an inventive approach that takes advantage of the strong fluorescence of the reference ligand. An example of application of the Macromolecule Competition Titration method for binding of nonfluorescent single-stranded nucleic acid poly(dA) to DnaB helicase is presented in Figure 7. The observed fluorescence signal was due to the poly(dεA), an etheno derivative of poly(dA), used as a reference. This method allows the determination of absolute average binding density and construction of a model-independent true binding isotherm.

Figure 6 Example of the protein–ligand binding study followed by fluorescence. Individual spectra of NADH when free in solution (N), bound in a binary complex with horse liver alcohol dehydrogenase ((a) SN; (b) PN and PN_2), and in a ternary complex in the presence of isobutyramide ((a) SNI; (b) PNI, PN_2I and PN_2I_2), along with corresponding equilibrium binding constants, were obtained with the help of the SPECTRABIND program of Toptygin and Brand.[76] Fluorescence spectra presented in (a) and (b) are obtained from the same titration data sets using two different binding models. Both models assume that the two binding sites (one on each of the identical subunits of the protein dimer) are identical and independent in terms of association constants. Model (a) also assumes that binding to the two sites is also spectroscopically independent. See text and Toptygin and Brand[76] for details. (Reproduced by permission of Academic Press, Inc.)

3.3 Membrane Proteins and Peptides

Determination of membrane organization and dynamics is one of the most challenging problems of structural biology because many methods (even of low resolution) developed for water-soluble systems are not directly applicable to membranes. For example, while the position of the fluorescence spectrum of tryptophan in a globular protein indicates a degree of exposure to the aqueous phase, it will not be sensitive to exposure to the

Figure 7 Example of protein–ligand interactions followed by means of fluorescence spectroscopy. The exceptional sensitivity of fluorescence is utilized in a variety of binding studies using one of the linear-response spectroscopic functions (e.g. intensity at a constant wavelength). Normally the fluorescence of the protein or ligand is altered as a result of the interaction. Jezewska and Bujalowski[78] have introduced a Macromolecule Competition Titration Method to study those interactions that do not directly result in such changes of fluorescence. Instead, the fluorescence of the reference ligand (an etheno derivative of a polynucleotide in this case) is measured in the presence of various concentrations of the ligand under study (nonlabeled polynucleotide). Fluorescence increase, plotted as a function of the protein concentration (DnaB helicase, symbols), is fitted using a binding model (solid lines) to calculate various parameters. Binding constants, parameters of cooperativity of binding and stoichiometry can be studied by fluorescence titration methods. (Reproduced by permission of the American Chemical Society.)

Figure 8 Set of bromolipids utilized to examine membrane penetration of proteins and peptides. Selective labeling of different positions along one of the acyl chains with bromine atoms, which are capable of quenching fluorescence via dynamic collisional mechanism,[42] allows the transverse position of the fluorophore to be determined. Two bromine atoms (large spheres) per lipid are attached in neighboring positions. This ''molecular ruler'' has been calibrated in an independent diffraction experiment yielding the distances (given in angstroms) from bromines to the bilayer center.[86] Depth-dependent fluorescence quenching profiles measured utilizing bromolipids can be evaluated with the help of distribution analysis[70,87,88] (see Figure 9 for examples) to obtain a variety of structural information.

lipid phase in a membrane-bound protein. Therefore, new approaches should be developed for structural studies in membranes. The depth-dependent fluorescence quenching technique is a useful tool to explore the structure of membrane proteins and peptides along the depth coordinate.[74,80–85] To achieve this objective it utilizes lipids with bromine atoms (Figure 8) or spin labels selectively attached to certain positions along acyl chains. This is a dynamic quenching resulting in decrease of both intensity and lifetime.[42,71]

In a depth-dependent fluorescence quenching experiment one normally determines the fluorescence intensity, F, of a probe as a function of the known depth of the quencher, h. Data are usually normalized to the intensity in the absence of quenching, F_0. Distribution analysis is one of the methods that can be used to quantitate the quenching in order to extract information on membrane penetration. It assumes that the quenching profile can be approximated by a symmetrical double-Gaussian function, which accounts for *cis*- and *trans*-leaflet quenching,[70,87] as shown in Equations (12) and (13):

$$\ln \frac{F_0}{F(h)} = G(h, \sigma, S) + G(-h, \sigma, S) \qquad (12)$$

$$G(h, \sigma, S) = \frac{S}{\sigma\sqrt{2\pi}} \exp\ -\frac{(h - h_m)^2}{2\sigma^2} \qquad (13)$$

where h_m, σ and S are the three fitting parameters: mean position, dispersion and area, respectively.

The position of the maximum represents the most probable transverse location of the fluorophore, while dispersion arises from the several broadening terms, such as finite size of the probe and the quencher and fluctuational distribution of their depth due to thermal motion. Multiple conformations will result in additional broadening of the profile. Equation (14) shows that the area under the quenching profile is a product of the inherent quenching constant, γ, determined by the nature of the quenching mechanism, excited state lifetime in the absence of quenching, τ, the degree to which the probe is exposed to a lipid phase, w, and the concentration of the quencher, C:

$$S = \gamma w \tau C \qquad (14)$$

Variation of exposure arising from the shielding of tryptophan side chains by the protein moiety provides important structural information on protein conformation

in the lipid bilayer. Equation (15) shows that the relative exposure, Ω, can be estimated as the ratio of absolute exposures of tryptophan residue in a protein, w_P, to that in a model compound (e.g. tryptophan octyl ester[42,88]), w_M:

$$\Omega = \frac{w_P}{w_M} = \frac{S_P \tau_M}{S_M \tau_P} \approx \frac{S_P Q_M}{S_M Q_P} \qquad (15)$$

If the lifetime measurements are not available, the ratio of τ values can be approximated by the ratio of quantum yields, Q, of a protein and a model compound in a nonquenching lipid membrane.

Application of the distribution analysis technique to a mutant cytochrome b_5 and to a model membrane-spanning peptide are presented in Figure 9. A single fluorophore of the membrane-binding peptide of cytochrome b_5 mutant, Trp-108, was found to be located close to the membrane interphase and its distribution along the depth coordinate is relatively narrow, suggesting the lack of conformational freedom.[70,87] The relative exposure of Trp-108 to lipid phase equals 0.66, as compared to tryptophan octyl ester. A single tryptophan in a membrane-spanning peptide is located deep in the hydrophobic core of the bilayer. For this peptide, the use of a double-Gaussian fitting function was especially important due to strong trans-leaflet quenching. Thus for this peptide the unimodal distribution of transverse position (Figure 9) differs from that of a quenching profile.

It has been demonstrated that all three parameters – average depth of the tryptophan, the width of its transverse distribution and the degree of its exposure to the lipid phase – are different in various proteins and peptides. Studies of melittin and various mutants of cytochrome b_5 and of outer membrane protein A indicate that these parameters can be altered by temperature-induced conformational change or during the kinetic insertion and folding.[70–73,88]

Another important aspect of the structural characterization of membrane proteins and peptides is determination of their topology. The critical issue is: Does a particular peptide equilibrate freely across the bilayer, form a stable transmembrane structure, or remain only on one surface? Recently Wimley and White[91] have developed a method that uses fluorescence quenching arising from resonance energy transfer for determining the topology of the tryptophan residues of peptides partitioned into phospholipid bilayer vesicles. This is accomplished through the use of a novel lyso-phospholipid quencher, lyso-methylcoumarin (LysoMC). Methylcoumarin quenches the fluorescence of membrane-bound tryptophan by the long-range resonance energy transfer mechanism with an apparent Förster distance that is comparable to the thickness of the hydrocarbon core of a lipid bilayer (~25 Å). Consequently, the methylcoumarin acceptor predominantly quenches tryptophans that reside in the same monolayer as the probe. The topology of a peptide's tryptophan in membranes can be determined by comparing the quenching in symmetric and asymmetric LysoMC-labeled vesicles (Figure 10).

Figure 9 Examples of structural studies of membrane proteins and peptides using depth-dependent fluorescence quenching. Symbols represent quenching data for (a) membrane-spanning peptide[89] and (b) cytochrome b_5 mutant[90] obtained with a set of bromolipids (Figure 8). Dashed lines are the fitting curves of the distribution analysis[70,87,88] utilizing Equations (12) and (13). Solid lines are the individual Gaussian components with three parameters h_m, σ and S, representing average position of the fluorophore in the lipid bilayer, heterogeneity of its transverse penetration, and quenching efficiency, respectively.

Both structural and thermodynamic studies on membrane proteins are clearly lagging behind those of their soluble counterparts. Only recently have the first basic principles of integral protein structure and stability begun to emerge.[77,92] The general reason for this is that the lipid bilayer membrane appears to be too large and

Figure 10 Schematic representation of the resonance energy transfer method of Wimley and White[91] for the determination of the topology of tryptophan in a membrane protein. LysoMC, which acts as the acceptor of electronic energy of tryptophan via long-range Förster mechanism, can be easily incorporated into large unilamellar vesicles either symmetrically (a) or asymmetrically (b). Comparison of the efficiency of energy transfer reveals the topology of the tryptophan.

slow-tumbling for solution NMR studies and too ''two-dimensional'' for X-ray crystallography. These limitations hindering applicability of high-resolution structural techniques do not compromise in principle the application of fluorescence and other spectroscopic methods (e.g. EPR[93]). Therefore, in addition to its traditional role as a technique sensing dynamic fluctuational aspects of protein structure and its kinetic metamorphoses, fluorescence spectroscopy is assuming a new role as a direct structural tool in studies of membrane proteins.

ACKNOWLEDGMENTS

I am very grateful to Drs L. Brand, W.M. Bujalowski, E.A. Burstein, A.E. Johnson, D. Toptygin, S.H. White and W.C. Wimley for providing me with the original figures from their publications, to Dr P.W. Holloway for creating an image of brominated lipids, and to Mr M.A. Myers for proofreading and editing the manuscript. During writing I was supported by grant GM-46823 (Prof S.H. White, PI) from the NIH. I would like to dedicate this contribution to Profs G. Weber, S.V. Konev, M. Kasha, L. Brand and E.A. Burstein who shaped my understanding of fluorescence phenomena by memorable conversations and by their groundbreaking research.

Infrared (IR) spectroscopy is one of the two forms of vibrational spectroscopy, the other being Raman spectroscopy. IR spectroscopy measures absorptions of vibrating molecules and yields information about molecular structures and structural interactions. The development of computerized Fourier transform infrared (FTIR) techniques has opened up new dimensions in biological IR spectroscopy owing to the increase in achievable signal-to-noise ratios, wavenumber accuracy, and data aquisition rates, and the ability to perform measurements with strongly absorbing samples. High-quality FTIR spectra can be obtained with relative ease and rapidly with very small amounts of sample in a variety of environments. Measurements of proteins in aqueous solution are almost routine now, and can be performed under equilibrium and nonequilibrium conditions. There are many IR absorption bands characteristic of peptide groups and amino acid side-chain groups from which information on protein structures can be obtained. The information provided by FTIR spectroscopy may be a global one or highly specific for a single vibrating chemical group. In some cases, the usefulness of the method is limited by difficulties in extracting the structural information contained in the IR absorption bands.

1 INTRODUCTION

Over the last few decades, IR spectroscopy has incorporated technological advances in physics, biochemistry, engineering, computer science, and molecular biology to become an invaluable tool in structural biology. FTIR spectroscopy now provides molecular information in systems ranging from small peptides and isolated enzymes

to peptide–protein complexes and membrane proteins. The information can either be highly specific for a single vibrating group in an enzyme or it may report global changes, e.g. due to some experimental procedure. Furthermore, the process of obtaining structural information is not restricted to a static picture but can also be achieved in real time by applying time-resolved IR techniques. An important feature to that, the size of a protein or the nature of the environment does not limit the application of FTIR spectroscopy. Measurements can be performed in aqueous solution or organic solvents, in oriented films or dispersions, and in detergents or membrane-like environments. High-quality spectra can rapidly be aquired (seconds to minutes) and require only relatively small amounts of protein sample (as low as 10–100 μg). Advances in instrumentation and numerical data analysis today permit the quantification of protein secondary structures from IR spectra. One of the strengths of FTIR spectroscopy in this respect is the sensitivity to assess, in relative terms, the extent and nature of changes in secondary and tertiary structure of peptides and proteins. The effects of environmental factors, point mutations, or ligand binding on the structure of soluble proteins or enzymes can be examined with high sensitivity by using peptide backbone and side-chain IR bands as conformation-sensitive monitors. Changes in external factors (such as temperature) and data aquisition may be performed under computer control, thereby permitting the design of complex experiments using automatic scanning under highly reproducible conditions. In addition to the normal spectroscopic analysis, these types of experiments can also provide typical structural and standard thermodynamic parameters of proteins and enzymes.

FTIR spectroscopy has proven to be particularly valuable for studying membrane-associated peptides and proteins, since they are often difficult or impossible to investigate by other spectroscopic methods (e.g. owing to light scattering artifacts, solubility, and structural integrity). Beyond the ability to measure even large membrane proteins, IR spectroscopy also allows the study of lipids and membrane proteins simultaneously, without the use of marker molecules or extra probes. Morever, polarized IR spectroscopy on oriented samples can provide structural information on the orientation of polypeptide chains within the membrane environment.

2 HISTORICAL OVERVIEW

IR spectroscopy is one of the earliest experimental methods recognized as potentially useful in providing information on structural features of peptides and proteins. As early as 1950 it was demonstrated that a strong correlation exists between the position of certain bands in IR spectra of homopolypeptides and their secondary structure.[1] Later, these experimental observations were refined by making detailed vibrational analyses of these structure-sensitive amide bands in order to establish a correlation between the frequencies of these bands and the type of secondary structure, such as purely α-helical or purely β-sheet structures.[2,3] Nine such IR bands exist, which are assigned as amide A, amide B and amides I–VII, in order of decreasing frequency[3,4] (Table 1).

Table 1 Characteristic IR bands of the peptide linkage

Designation (amide)	Approximate frequency (cm^{-1})	Description
A	~3300	NH stretching in resonance with first amide II overtone
B	~3100	
I	1610–1695	CO stretching
II	1480–1575	NH bending and CN stretching
III	1220–1320	CN stretching and NH bending
IV	625–765	OCN bending, mixed with other modes
V	640–800	Out-of-plane NH bending
VI	535–605	Out-of-plane CO bending
VII	~200	Skeletal torsion

Of all the amide bands, the most intense and most useful for the analysis of the secondary structure of proteins was found to be the amide I band, which occurs in the region 1600–1700 cm^{-1}. In contrast to the other amide vibrations, this band reflects an almost pure vibrational character, since it consists mainly of the carbonyl stretching vibration mode of the amide group. Figure 1(a) and (b) illustrates the different IR spectroscopic characteristics of the amide I band for two proteins fundamentally different in their secondary structure. The α-helically structured myoglobin shows a relatively sharp band centered at 1654 cm^{-1} (a), whereas the antiparallel β-sheet structured concanavalin A displays an asymmetrically shaped amide I band with a maximum at 1635 cm^{-1} and a weaker feature at 1694 cm^{-1} (b).

Despite the well-recognized potential of the amide I band for conformational studies, interest in the IR spectroscopy of proteins remained limited for nearly three decades. Experimental conditions made it difficult to obtain reproducible spectra and to extract the structural information encoded in the IR bands. Major drawbacks that prevented widespread use of IR spectroscopy in the past were (i) the poor sensitivity and reproducibility of the classical dispersive IR spectrometers, which recorded spectra with low signal-to-noise ratio and low

Figure 1 The amide I band of the α-helical protein myoglobin (a) and the β-sheet protein concanavalin A (b), as measured by IR spectroscopy in H_2O.

wavenumber accuracy, (ii) strongly interfering absorptions from the surrounding media or solvents such as water, and the difficulty of completely subtracting their contributions from the protein spectrum to reveal the weak IR bands of the protein, and (iii) the difficulty of extracting structural information contained in the IR amide bands. The first two constraints have largely been overcome by the development of FTIR spectrometers, which are far superior to dispersive IR instruments in their high energy throughput, achievable signal-to-noise ratio ($>10\,000:1$), wavenumber accuracy ($0.01\,cm^{-1}$), and data processing capabilities. The third difficulty, however, is of a more fundamental nature. Since the polypeptide backbone of proteins is normally folded in more than one conformation, amide bands of these proteins result from the superposition of bands corresponding to the different types of secondary structure such as helical, sheet, and unordered/loop structures. Moreover, the spectral features of the amide bands also vary slightly for each type of secondary structure, depending on environment, structural distortion, and domain interactions. All this illustrates the extraordinarily high conformational sensitivity of these amide modes as being specific for each protein, but it also creates at the same time the difficulty that these individual band components cannot easily be classified and quantified in more general terms of secondary structure.

In the last decade, different methods for determining the secondary structural composition of a protein by mathematical manipulation of the experimental data have been developed, each of them with certain weaknesses[5] as described later in this article. In contrast to these indirect methods, a new, different, and very promising direct approach has been applied, which is based on the introduction of isotopic labeling of specific sites of the polypeptide chain.[6] This allows FTIR spectroscopy to locate a particular secondary structure within the polypeptide chain and helps in analyzing conformational changes that originate exclusively from the labeled site. Since most of the IR labels have no structural consequences [similar to ^{13}C-labeling experiments in nuclear magnetic resonance (NMR) spectroscopy] and isotopic replacement is relatively easily achieved by chemical synthesis of peptides and is biosynthetically feasible for proteins, the behavior of single amino acids or even atoms can be monitored within intact peptides or proteins. This information can be obtained in real time by applying different time-resolved FTIR techniques, which closes the gap between this methodology and visible and fluorescence spectroscopy.

3 INSTRUMENTAL TECHNIQUES AND SAMPLE PROCEDURES

3.1 General Considerations

Water (as one of the strongest IR-absorbing molecules) restricts the measurement of IR bands of molecules in biological water-containing systems if they occur in the range between 1600–1700 and 3100–3700 cm^{-1} where water shows the strongest IR bands. Most of the early experiments were therefore limited to sample preparations in which the water was partially reduced or completely removed. Samples were prepared as dehydrated protein films deposited on IR-transparent substrates or as solid protein powders ground and pressed into potassium bromide pellets. These experiments should be regarded as good preliminary tests, but were of only limited relevance due to the nonphysiological nature of the measurements. Today's sample preparations aim for the measurement of molecules in buffer solutions, which is permitted by the described inherent advantages of FTIR spectroscopy.

To record a spectrum of a sample in H_2O buffer solution, very short pathlength cells of 3–8 µm are required, to prevent total IR absorption in the spectral regions of the water. According to the Lambert–Beer law, such short pathlengths limit the intensities of the IR bands and the signal-to-noise ratio at a given sample concentration. Consequently, relatively high sample concentrations ($>10\,mg\,mL^{-1}$) are required for the measurement. To obtain the spectrum of a sample, digital subtraction of solvent/buffer absorptions from the spectrum of the sample is required. For appropriate subtraction, the spectrum of the solvent/buffer should be recorded under conditions (such as temperature, ionic strength, pH, number of scans, resolution, etc.) identical with those of the sample spectrum. In practice, identical physico-chemical parameters are very important for this procedure since variations will certainly cause changes to spectral features of the H_2O bands, preventing an ideal subtraction of the spectral buffer contributions.

Figure 2 (a) IR spectra of ribonuclease (RNase) T1 in H_2O buffer at a protein concentration of 28 mg mL^{-1} (dashed line) and 7 mg mL^{-1} (dotted line), together with the buffer spectrum (solid line). (b) IR spectra of RNase T1 after subtraction of the buffer spectrum.

For instance, the temperatures of the sample in aqueous solution and the solvent should coincide within 0.1 °C in order to avoid artifacts caused by temperature differences.

Figure 2(a) shows IR spectra of the enzyme RNase T1 in H_2O buffer at two different concentrations. For these transmission measurements, a micro drop of 2 µL of the enzyme solution (7 or 28 mg mL^{-1}) was placed between a pair of calcium fluoride (CaF_2) windows separated by a pathlength of 8 µm. The solvent spectrum (Figure 2a, solid line) was measured in an optimally matched second cell of slighly reduced pathlength, which takes into account the slightly lower water concentration in the protein sample measured. Among the IR window materials available for experiments in solution, CaF_2 is the most common because (i) it has a low refractive index which is similar to that of water (high light throughput, low tendency for interference fringe pattern in the spectra); (ii) it is relatively rugged; and (iii) it is transparent to IR light (>1000 cm^{-1}) as far as the ultraviolet (UV) region of the spectrum. Barium fluoride (BaF_2), a similar window material, has a lower spectral cutoff than CaF_2 (at ~800 cm^{-1}), enabling additional IR spectral bands to be observed, but it is less rugged than CaF_2 and significantly more soluble in aqueous solution. Others [such as ZnSe, thallium iodide (KRS-5), AgCl, or Irtran] are characterized by unfortunately high refractive indices, which results in major reflection losses and persistent fringing in the spectra.

Although CaF_2 is the most suitable window material for protein measurements, it is not an ideal window material for long-term measurements of calcium-binding proteins. The solubility of CaF_2 in water is very low, but possible contamination of the sample by dissolution of Ca^{2+} from the CaF_2 window cannot completely be excluded. In direct consequence, the Ca^{2+}-free form of a sample may not persist during the collection of spectra over longer timescales. Nevertheless, flow-through demountable cells with Luer-lock fittings, CaF_2 windows and spacers covering pathlengths from 6 to 200 µm are often used for protein measurements. These cells are available from virtually any IR accessories supplier, but reveal some disadvantages in practice such as being difficult to clean, accidental injection of gas bubbles and the application of high pressure in the case of short pathlength cells.

To circumvent these problems, our design of a custom-made IR cell consists of a flat cover disk (w_1, typically made of CaF_2) and a second disk of the same material (w_2), with the center hollowed out to form a recessed parallel surface surrounded by a groove (see Figure 3). The groove (gr) prevents direct contact of the sample with the outer part of the disk. Pressing the cover disk (w_1) on to the sample disk (w_2) is sufficient to prevent the evaporation of water for many hours at room temperature and seals the cell. Two spacer discs (g_1 and g_2) e.g. made of lead or graphite are used as gaskets to fit the windows into the base mounting (h_2), which is then sealed with the lid mounting (h_1). For measurements at higher temperatures and/or for long-term experiments, the sealing surface of the disks is lubricated with mineral oil dissolved in a volatile organic solvent prior to filling and assembling the cell. This prevents both evaporation of the solvent (e.g. water) at high temperatures (e.g. 95 °C), for up to several weeks, or changes of the isotope content when working with deuterium oxide

Figure 3 Schematic representation of our custom-made IR cell used to record spectra from samples in aqueous solutions or as dispersions.

(D_2O) solutions. For temperature control, the gas-tight IR cell is placed into a jacket through which heating or cooling liquid from an external bath circulates. The temperature is monitored at the jacket/cell interface with a thermocouple (t).

Depending upon the diameter and the depth of the recessed surface of the window (i.e. the pathlength of the cell), only a few microliters are required to fill the cell. Moreover, this type of cell can very easily be filled with solution, assembled and disassembled, cleaned between measurements, and provides a constant pathlength, which is very difficult to achieve with conventional tin or polyethylene spacers. The pathlength of the cell can be estimated very precisely by measuring the phase difference in interference fringes caused by internal light reflection of the window surfaces in the empty cell. The relationship between the pathlength of the cell (in centimeters) and the peak-to-peak fringes (ripples) in the spectrum is given by Equation (1):

$$\text{pathlength} = \frac{n}{2}(\nu_1 - \nu_2) \qquad (1)$$

where n represents the number of complete peak-to-peak fringes between two maxima (or minima) at the wavenumbers ν_1 and ν_2 (in cm^{-1}). From a practical point of view, it is interesting to note that all IR transmission cells, if made from suitable high-quality window material, can also be used for measurements in the visible to far-UV spectral region. This allows a variety of measurements such as IR, circular dichroism (CD), and absorption spectra, of the same sample prepared in the same sampling cell.

3.2 The Role of Water in Buffer Subtraction from Protein Spectra

The dominance of water in the spectra of proteins in water-buffered solutions is demonstrated in Figure 2(a), comparing the IR spectra of RNase T1 with a spectrum of the H_2O-based buffer solution applied in the experiment. Whereas some additional spectral features can be seen in the spectrum of the concentrated protein sample ($28\,mg\,mL^{-1}$), the original spectrum of the protein at a lower concentration of $7\,mg\,mL^{-1}$ (dotted line) is practically indistinguishable from the spectrum of the buffer (solid line). The actual protein bands can only be seen after subtracting the H_2O buffer spectrum from the protein spectrum when measured under identical conditions (Figure 2b). A fourfold increase in protein concentration consistently results in a difference spectrum of higher spectral quality, in which all of the major absorptions expected in the IR spectra of proteins can be identified, but not all proteins tolerate this relatively high concentration without self-association or aggregation.

The precision of the subtraction of water from a protein spectrum requires a reference water band that does not overlap with those of the sample. Often, the combination band of water at around $2126\,cm^{-1}$ is used to ensure proper subtraction of water, which then results ideally in a straight baseline between 1900 and $2400\,cm^{-1}$. If positive or negative features are visible in the $2100\,cm^{-1}$ region of the water-subtracted spectrum, incomplete or overcompensation of the water features is indicated. If derivative-type artifacts are observed in this region (positive and negative bands), this implies that the spectroscopic characteristics of the water in the sample water are not identical with those of the reference water. The latter artefact may often be observed at very high protein concentrations ($>50\,mg\,mL^{-1}$), since the interaction of a protein with water can cause the creation of hydration shells around the protein and therefore modify the water vibrations and hence the shape of the water bands in the IR spectrum. Consequently, the reference spectrum of the H_2O buffer cannot completely match the spectral conditions of the water in the protein solution (containing bulk water plus protein-bound water). While the weak water band at $2126\,cm^{-1}$ (which is more than six times less intense than the water band of interest at around $1645\,cm^{-1}$) may serve as a good approximation to subtract the water features interactively, it is necessary to perform the final water subtraction based on a different spectral region with stronger water absorptions. The side lobes of the strong water band of the stretching vibrations (range $3000–3700\,cm^{-1}$) are ideal for this subtraction.

Peptides or proteins have only very weak IR bands in the 3000–3100 cm^{-1} region (see Figure 2b). Residual absorbance in the difference spectrum at 3080–3100 or ~3650 cm^{-1} may serve as a very sensitive monitor for incomplete water compensation.

3.3 Effects and Consequences of the Replacement of Water with Deuterium Oxide in Buffers

One way of overcoming the problems related to the strong water absorbance in the amide I region is to replace H_2O in the buffer with D_2O. The IR bands of D_2O occur at lower wavenumbers than those of H_2O, owing to the downshifted vibrations of the almost twice as heavy deuterium atoms. This isotopic effect creates a region of relatively low absorbance between 1400 and 1800 cm^{-1}, an ideal window for observing the weak IR bands of the dissolved peptide or protein. Much longer pathlengths of 40–80 μm may then be used, hence much lower sample concentrations are required to obtain high-quality spectra, which is of particular practical interest for proteins of low solubility. Figure 4(a) shows IR spectra of RNase T1 in D_2O buffer at protein concentrations of 14 (dashed line) and 1.4 mg mL^{-1} (dotted line), together with the spectrum of the D_2O buffer (solid line). The buffer-subtracted spectrum (Figure 4b) illustrates that a spectrum with a good signal-to-noise ratio may be obtained from 10 μL of a 1.4 mg mL^{-1} protein solution prepared in an IR transmission cell with a 45 μm pathlength. Measurements of lower protein concentrations are feasible, but below values of approximately 0.5–1 mg mL^{-1} the noise in the spectra becomes too great to enable some of the approaches described later in this article to be applied. A specific feature of protein studies in D_2O is the exchange of amide protons into deuterons, which in consequence causes changes in the spectrum after a peptide or protein has been introduced into D_2O. The most dramatic change is a substantial decrease in the intensity of the amide II band (predominantly originating from peptide N–H bending modes, coupled with C–N stretching modes) which is centered near 1545 cm^{-1} in H_2O. This band shifts down in frequency by nearly 100 cm^{-1} to 1450 cm^{-1} (amide II′) in D_2O, thereby revealing side-chain vibration bands of the protein such as those of arginine, tyrosine, aspartic acid and glutamic acid in the range 1490–1610 cm^{-1}. The intensity changes of the amide II band of a protein in D_2O can be efficiently used to monitor hydrogen–deuterium exchange, providing valuable information concerning the structure and flexibility of a protein.
